Etravirine (ETR)/ Intelence	200 mg PO BID	No dosage adjustment necessary	Child-Pugh Class A or B: no dosage adjustment Child-Pugh Class C: no dosage recommendation
Nevirapine (NVP)/ Viramune	200 mg PO BID	HD patients: limited data; no dosage recommendation	Child-Pugh Class B or C: contraindicated
Protease Inhibitors			
Atazanavir (ATV)/ Reyataz	400 mg PO once daily or (ATV 300 mg + RTV 100 mg) PO once daily	No dosage adjustment for patients with renal dysfunction not requiring HD ARV-naïve patients on HD: (ATV 300 mg + RTV 100 mg) once daily ARV-experienced patients on HD: ATV or RTV-boosted ATV not recommended	**Child-Pugh Score** **Dose** 7–9 300 mg once daily >9 not recommended RTV boosting is **not** recommended in patients with hepatic impairment (Child-Pugh Score ≥7).
Darunavir (DRV)/ Prezista	(DRV 800 mg + RTV 100 mg) PO once daily (ARV-naïve patients) or (DRV 600 mg + RTV 100 mg) PO BID	No dosage adjustment necessary	Mild to moderate hepatic impairment: no dosage adjustment Severe hepatic impairment: not recommended
Fosamprenavir (FPV)/ Lexiva	1,400 mg PO BID or (FPV 1,400 mg + RTV 100–200 mg) PO once daily or (FPV 700 mg + RTV 100 mg) PO BID	No dosage adjustment necessary	**Child-Pugh Score** **Dose** PI-naïve patients only: 5–9 700 mg BID 10–15 350 mg BID PI-naïve or PI-experienced patients: 5–6 700 mg BID + RTV 100 mg once daily 7–9 450 mg BID + RTV 100 mg once daily 10–15 300 mg BID + RTV 100 mg once daily
Indinavir (IDV)/ Crixivan	800 mg PO q8h	No dosage adjustment necessary	Mild to moderate hepatic insufficiency because of cirrhosis: 600 mg q8h
Lopinavir/ritonavir (LPV/r) Kaletra	400/100 mg PO BID or 800/200 mg PO once daily	Avoid once daily dosing in patients on HD	No dosage recommendation; use with caution in patients with hepatic impairment
Nelfinavir (NFV)/ Viracept	1,250 mg PO BID	No dosage adjustment necessary	Mild hepatic impairment: no dosage adjustment Moderate to severe hepatic impairment: do not use
Ritonavir (RTV)/ Norvir	As a PI-boosting agent: 100–400 mg per day	No dosage adjustment necessary	Refer to recommendations for the primary PI
Saquinavir (SQV)/ Invirase	(SQV 1,000 mg + RTV 100 mg) PO BID	No dosage adjustment necessary	Mild to moderate hepatic impairment: use with caution Severe hepatic impairment: contraindicated
Tipranavir (TPV)/ Aptivus	(TPV 500 mg + RTV 200 mg) PO BID	No dosage adjustment necessary	Child-Pugh Class A: use with caution Child-Pugh Class B or C: contraindicated

Appendix B, Table 7. Antiretroviral Dosing Recommendations in Patients with Renal or Hepatic Insufficiency
Page 3 of 3

Antiretrovirals Generic Name (abbreviation)/ Trade Name	Daily Dose	Dosing in Renal Insufficiency	Dosing in Hepatic Impairment
Fusion Inhibitor			
Enfuvirtide (T20)/ Fuzeon	90 mg subcutaneous BID	No dosage adjustment necessary	No dosage adjustment necessary
CCR5 Antagonist			
Maraviroc (MVC)/ Selzentry	The recommended dose differs based on concomitant medications because of drug interactions. See **Appendix B, Table 6** for detailed dosing information.	**CrCl <30 mL/min or HD** Without potent CYP3A inhibitors or inducers: 300 mg BID; reduce to 150 mg BID if postural hypotension occurs With potent CYP3A inducers or inhibitors: not recommended	No dosage recommendations. Concentrations will likely be increased in patients with hepatic impairment.
Integrase Inhibitor			
Raltegravir (RAL)/ Isentress	400 mg BID	No dosage adjustment necessary	Mild to moderate hepatic insufficiency: no dosage adjustment necessary Severe hepatic insufficiency: no recommendation

Creatinine Clearance Calculation	
Male: $\frac{(140 - \text{age in years}) \times \text{weight (kg)}}{72 \times \text{Serum Creatinine}}$	Female: $\frac{(140 - \text{age in years}) \times \text{weight (kg)} \times 0.85}{72 \times \text{Serum Creatinine}}$

Child-Pugh Score			
Component	**Points Scored**		
	1	**2**	**3**
Encephalopathy*	None	Grade 1–2	Grade 3–4
Ascites	None	Mild or controlled by diuretics	Moderate or refractory despite diuretics
Albumin	>3.5 g/dL	2.8–3.5 g/dL	<2.8 g/dL
Total bilirubin or	<2 mg/dL (<34 μmol/L)	2–3 mg/dL (34 μmol/L to 50 μmol/L)	>3 mg/dL (>50 μmol/L)
Modified total bilirubin†	<4 mg/dL	4–7 mg/dL	>7 mg/dL
Prothrombin time (seconds prolonged) or	<4	4–6	>6
International normalized ratio (INR)	<1.7	1.7–2.3	>2.3

* Encephalopathy Grades
Grade 1: Mild confusion, anxiety, restlessness, fine tremor, slowed coordination
Grade 2: Drowsiness, disorientation, asterixis
Grade 3: Somnolent but rousable, marked confusion, incomprehensible speech, incontinence, hyperventilation
Grade 4: Coma, decerebrate posturing, flaccidity
† Modified total bilirubin used to score patients who have Gilbert's syndrome or who are taking indinavir or atazanavir

Child-Pugh Classification	Total Score*
Class A	5–6 points
Class B	7–9 points
Class C	>9 points

* Sum of points for each component

Disclosure of Relationship

CDC, our planners, and our content specialists wish to disclose they have no financial interests or other relationships with the manufacturers of commercial products, suppliers of commercial services, or commercial supporters, with the exception of Constance Benson and King K. Holmes. Dr. Benson discloses being on the Advisory Board for Merck, GlaxoSmithKline, and Boehringer Ingelheim; being a grant recipient for Gilead; and being a Data Safety Monitoring Board (DSMB) member for Achillion and JJR Australia. Her spouse also is a consultant for Merck, Gilead, Achillion, Monogram, and Vertex. Dr. Holmes discloses being a DSMB member of Merck, receiving an honorarium at the 2005 Infectious Diseases Society of America Conference, and serving on the Mycology Research Laboratories scientific advisory board. Presentations will not include any discussion of the unlabeled use of a product or a product under investigational use.

Guidelines for Prevention and Treatment of Opportunistic Infections in HIV-Infected Adults and Adolescents

Summary

This report updates and combines earlier versions of guidelines for the prevention and treatment of opportunistic infections (OIs) in HIV-infected adults (i.e., persons aged ≥18 years) and adolescents (i.e., persons aged 13–17 years), last published in 2002 and 2004, respectively. It has been prepared by the Centers for Disease Control and Prevention (CDC), the National Institutes of Health (NIH), and the HIV Medicine Association (HIVMA) of the Infectious Diseases Society of America (IDSA). The guidelines are intended for use by clinicians and other health-care providers, HIV-infected patients, and policy makers in the United States. These guidelines address several OIs that occur in the United States and five OIs that might be acquired during international travel. Topic areas covered for each OI include epidemiology, clinical manifestations, diagnosis, prevention of exposure; prevention of disease by chemoprophylaxis and vaccination; discontinuation of primary prophylaxis after immune reconstitution; treatment of disease; monitoring for adverse effects during treatment; management of treatment failure; prevention of disease recurrence; discontinuation of secondary prophylaxis after immune reconstitution; and special considerations during pregnancy.

These guidelines were developed by a panel of specialists from the United States government and academic institutions. For each OI, a small group of specialists with content-matter expertise reviewed the literature for new information since the guidelines were last published; they then proposed revised recommendations at a meeting held at NIH in June 2007. After these presentations and discussion, the revised guidelines were further reviewed by the co-editors; by the Office of AIDS Research, NIH; by specialists at CDC; and by HIVMA of IDSA before final approval and publication.

The recommendations are rated by a letter that indicates the strength of the recommendation and a Roman numeral that indicates the quality of evidence supporting the recommendation, so that readers can ascertain how best to apply the recommendations in their practice environments.

Major changes in the guidelines include 1) greater emphasis on the importance of antiretroviral therapy for the prevention and treatment of OIs, especially those OIs for which no specific therapy exists; 2) information regarding the diagnosis and management of immune reconstitution inflammatory syndromes; 3) information regarding the use of interferon-gamma release assays for the diagnosis of latent Mycobacterium tuberculosis (TB) infection; 4) updated information concerning drug interactions that affect the use of rifamycin drugs for prevention and treatment of TB; 5) the addition of a section on hepatitis B virus infection; and 6) the addition of malaria to the list of OIs that might be acquired during international travel.

This report includes eleven tables pertinent to the prevention and treatment of OIs, a figure that pertains to the diagnois of tuberculosis, a figure that describes immunization recommendations, and an appendix that summarizes recommendations for prevention of exposure to opportunistic pathogens.

The material in this report originated in the National Center for HIV/AIDS, Viral Hepatitis, STD, and TB Prevention, Kevin Fenton, MD, Director.

Introduction

Before the widespread use of potent combination antiretroviral therapy (ART), opportunistic infections (OIs), which have been defined as infections that are more frequent or more severe because of immunosuppression in HIV-infected persons, were the principal cause of morbidity and mortality in this population. In the early 1990s, the use of chemoprophylaxis, immunization, and better strategies for managing acute OIs contributed to improved quality of life and improved survival (*1*). However, the widespread use of ART starting in the mid-1990s has had the most profound influence on reducing OI-related mortality in HIV-infected persons in those countries in which these therapies are accessible and affordable (*1–8*).

Despite the availability of ART in the United States and other industrialized countries, OIs continue to cause considerable morbidity and mortality for three primary reasons: 1) many patients are unaware of their HIV infection and seek medical care when an OI becomes the initial indicator of their disease; 2) certain patients are aware of their HIV infection, but do not take ART because of psychosocial or economic factors; and 3) certain patients are prescribed ART, but fail to attain adequate virologic and immunologic response because of factors related to adherence, pharmacokinetics, or unexplained biologic factors (*4,9,10*). Thus, although hospitalizations and deaths have decreased since the implementation of ART, OIs remain a leading cause of morbidity and mortality in HIV-infected persons (*11–19*). Clinicians must be knowledgeable about optimal strategies for prevention and management of OIs to provide comprehensive high-quality care for these patients.

Recognizing that the relation between OIs and HIV infection is bidirectional is important. HIV leads to immunosuppression that allows opportunistic pathogens to cause disease in HIV-infected persons. OIs and other coinfections that might be common in HIV-infected persons, such as sexually transmitted infections, can also have adverse effects on the natural history of HIV infection. Certain OIs are associated with reversible increases in circulating viral load (*20–25*), and these increases could lead to accelerated HIV progression or increased transmission of HIV (*26*). Thus, although chemoprophylaxis and vaccination directly prevent pathogen-specific morbidity and mortality, they might also contribute to reduced rate of progression of HIV disease. For instance, randomized trials using trimethoprim-sulfamethoxazole (TMP-SMX) have documented that chemoprophylaxis can both decrease OI-related morbidity and improve survival. The survival benefit is likely to be partially attributable to reduced progression of HIV infection (*27–31*). Reduced progression of HIV infection would also indirectly delay or reduce the occurrence of subsequent OIs.

History of the Guidelines

In 1989, the Guidelines for Prophylaxis against *Pneumocystis carinii* Pneumonia for persons infected with the human immunodeficiency virus became the first HIV-related treatment guideline published by the U.S. Public Health Service (*32*). This report was followed by a guideline on prevention of *Mycobacterium avium* complex (MAC) disease in 1993 (*33*). In 1995, these guidelines were expanded to include the prevention of all HIV-related OIs and the Infectious Diseases Society of America (IDSA) joined as a cosponsor (*34*). These prevention guidelines were revised in 1997, 1999, and 2002 and have been published in *MMWR* (*35–37*), *Clinical Infectious Diseases* (*38–40*), *the Annals of Internal Medicine* (*41,42*), *American Family Physician* (*43,44*), and *Pediatrics* (*45*); accompanying editorials have appeared in the *Journal of the American Medical Association* (*46,47*).

In 2004, CDC, the National Institutes of Health (NIH), and the HIV Medicine Association (HIVMA) of the IDSA published a new guideline including recommendations for treating HIV-infected adults and adolescents with OIs (*48*). Companion guidelines were published for HIV-infected children (*49*).

Responses to these guidelines (e.g., numbers of requests for reprints, website contacts, and observations from health-care providers) have demonstrated that these guidelines have served as valuable references for HIV health-care providers. Because the guidelines include ratings indicating the strength of each recommendation and the quality of supporting evidence, readers have been able to assess the importance of each recommendation. The present report includes recommendations for both prevention and treatment of OIs in HIV-infected adults and adolescents; an accompanying report includes recommendations for HIV-exposed and -infected children.

These guidelines are intended for clinicians, other health-care providers, HIV-infected patients, and policy makers residing in the United States; guidelines pertinent to other regions of the world, especially countries with limited resources, might differ regarding the spectrum of OIs of interest and their diagnostic and therapeutic capacity.

Guidelines Process

These guidelines were prepared by the Opportunistic Infections Working Group under the auspices of the Office of AIDS Research Advisory Council (OARAC) of NIH. Group leaders and team members with expertise in specific OIs were selected from the membership of the Working Group; each group reviewed the literature since the last publication of the prevention and treatment guidelines, conferred for several months, and produced draft revised guidelines.

Recommendations were reviewed and discussed by the Working Group at a meeting in Bethesda, Maryland, on June 25–26, 2007. A draft version of these recommendations was posted at AIDSInfo (http://aidsinfo.nih.gov/contentfiles/Adult_OI.pdf) on June 18, 2008. Since the June 18, 2008 posting, the draft recommendations were reviewed and updated for this report by Working Group members and subject matter experts. Suggested updates were reviewed by the co-editors, who amended the report, as warranted. The final version of the report was further reviewed by the co-editors, the Office of AIDS Research, NIH; experts at CDC; and the HIVMA of IDSA before final approval and publication.

The current guidelines share key features with prior versions. They are labeled as guidelines, indicating that the recommendations should be considered in the context of the individual patient situation and the community where the patient is being managed. They are evidence based. For each recommendation, the strength and quality of the evidence supporting it are indicated using a revised version of the rating system of the IDSA. As noted above, they have been developed by a broadly based panel that included representatives from academic medical centers, federal governmental agencies, community-based practices, and consumer advocates; representatives from Europe, Latin America, and Asia also took part in the process. The guidelines are available in print media and on the Internet. They are written for physicians and other health-care providers who care for HIV-infected persons in the United States and Western Europe where access is available to a full range of up-to-date medical services; however, these recommended strategies might not be feasible or appropriate in all settings where the spectrum of HIV-related complications and diagnostic capacity differ from those observed in the United States and Western Europe. Final versions of the guidelines were reviewed by respective members of each panel to ensure the recommendations were complete and appropriate. They are endorsed by CDC, the NIH, and the HIVMA of the IDSA. They are intended to complement more comprehensive textbooks, journals, and other relevant informational materials. Information is summarized in 11 tables.

Major Changes in Guidelines Since Last Publication

Major changes include 1) additional emphasis on the importance of ART for prevention and treatment of OIs, especially those for which specific chemoprophylaxis and treatment do not exist; 2) information on diagnosis and management of immune reconstitution inflammatory syndromes (IRIS); 3) information on interferon-gamma release assays (IGRAs) for the detection of latent *Mycobacterium tuberculosis* infection; 4) updated information on drug interactions affecting use of rifamycin drugs for prevention and treatment of tuberculosis (TB); 5) addition of a section on hepatitis B virus (HBV) infection; and 6) addition of a section on malaria to the OIs of geographic interest.

How to Use the Information in this Report

For each of the OIs discussed in this report, recommendations are provided that address 1) preventing exposure to opportunistic pathogens, 2) preventing disease, 3) discontinuing primary prophylaxis after immune reconstitution, 4) treating patients with disease, 5) monitoring for adverse effects (including IRIS), 6) managing treatment failure, 7) preventing

BOX. System used to rate the strength of recommendations and quality of supporting evidence

Rating	Strength of recommendation
A	Both strong evidence for efficacy and substantial clinical benefit support recommendation for use. Should always be offered.
B	Moderate evidence for efficacy—or strong evidence for efficacy but only limited clinical benefit—supports recommendation for use. Should generally be offered.
C	Evidence for efficacy is insufficient to support a recommendation for or against use. Or evidence for efficacy might not outweigh adverse consequences (e.g. drug toxicity, drug interactions) or cost of the treatment or alternative approaches. Optional.
D	Moderate evidence for lack of efficacy or for adverse outcome supports a recommendation against use. Should generally not be offered.
E	Good evidence for lack of efficacy or for adverse outcome supports a recommendation against use. Should never be offered.
Rating	**Quality of the evidence supporting the recommendation**
I	Evidence from at least one properly-designed randomized, controlled trial.
II	Evidence from at least one well-designed clinical trial without randomization, from cohort or case-controlled analytic studies (preferably from more than one center), or from multiple time-series studies, or dramatic results from uncontrolled experiments.
III	Evidence from opinions of respected authorities based on clinical experience, descriptive studies, or reports of expert committees.

disease recurrence ("secondary prophylaxis" or chronic maintenance therapy), 8) discontinuing secondary prophylaxis after immune reconstitution, and 9) special considerations during pregnancy. Recommendations are rated by a revised version of the IDSA rating system (Box). In this system, the letters A–E signify the strength of the recommendation for or against a preventive or therapeutic measure, and Roman numerals I–III indicate the quality of evidence supporting the recommendation. The guidelines include eleven tables pertinent to the prevention and treatment of OIs (Tables 1–11), a figure that pertains to the diagnosis of tuberculosis (Figure 1), a figure that describes immunization recommendations (Figure 2), and an appendix that summarizes recommendations pertinent to prevention of exposure to opportunistic pathogens.

Effect of ART on the Management of OIs

Clinicians treating HIV-infected patients often have to consider two questions related to OIs and ART: 1) when to initiate ART in ART-naïve persons who experience an acute OI, and 2) how ART should be managed for persons who are on ART but who experience an acute OI.

Initiation of ART in the Setting of an Acute OI (Treatment-Naïve Patients)

When an acute OI is present, initiation of ART is usually expected to improve immune function and contribute to faster resolution of the OI. Initiation of ART has been documented to be effective for OIs for which effective therapy does not exist; cryptosporidiosis, microsporidiosis, and progressive multifocal leukoencephalopathy (PML) might resolve or at least stabilize after the institution of effective ART (50–*52*). For Kaposi's sarcoma (KS), initiation of ART has been documented to lead to resolution of lesions in the absence of specific therapy for the sarcoma (*53*). The initiation of ART in the setting of an acute OI also has preventive benefit; a second OI is less likely to occur if ART is started promptly rather than delaying the initiation of ART.

Starting ART in the setting of an acute OI has several potential disadvantages. Severely ill patients might not absorb ART drugs, leading to subtherapeutic serum levels and the development of antiretroviral drug resistance. ART toxicities might be confused with disease manifestations or toxicities associated with drugs used for treating patients with an OI. Drug-drug interactions among ART and anti-OI drugs might be difficult to manage. Renal or hepatic dysfunction during acute OIs might make dosing of ART drugs difficult to estimate. Finally, IRIS events can occur and cause manifestations that are difficult to distinguish from other clinical conditions.

The term IRIS has been used to describe a group of clinical syndromes associated with immune reconstitution that have been observed most commonly for mycobacterial infections (TB and disseminated MAC disease), but also for other OIs, including *Pneumocystis jirovecii* pneumonia (PCP), toxoplasmosis, hepatitis B and hepatitis C viruses, cytomegalovirus (CMV) infection, varicella-zoster virus (VZV) infection, cryptococcal infection, histoplasmosis, and PML (*54–65*). IRIS manifestations are diverse and have not been defined precisely; they are usually characterized by fever and worsening of the clinical manifestations of the underlying OI. These clinical manifestations might be at the site of previously recognized opportunistic disease or might "unmask" disease at new sites not previously known to be infected by the pathogen. They also might represent a response to a previously unrecognized additional pathogen. The majority of patients who manifest IRIS do so within the first 4–8 weeks after starting ART, and have had high viral loads and low $CD4^+$ T-lymphocyte ($CD4^+$) counts. However, IRIS has occurred weeks after ART was started and in sequestered sites such as bone.

Diagnosis of IRIS is clinically challenging and involves differentiation from progression of the initial OI (including the possibility of antimicrobial resistance and treatment failure), development of a new OI, unrelated organ dysfunction, or drug toxicity. Therapy for IRIS has been empiric. No well-controlled trials exist to help decide when nonsteroidal drugs or corticosteroids are needed or when ART should be suspended. The inflammation might take weeks or months to subside. IRIS does not appear to have favorable or unfavorable implications about patient survival, with the possible exception of IRIS associated with cryptococcal meningitis (*66, 67*).

For these reasons, no consensus has been reached concerning the optimal time to start ART in the setting of a recently diagnosed OI. However, one recently completed randomized clinical trial has demonstrated a clinical and survival benefit of starting ART early, within the first 2 weeks, of initiation of treatment for an acute OI, excluding TB (*68*). The majority of OIs represented in this study were PCP and invasive bacterial infections, although cryptococcal, other fungal diseases, and disseminated MAC disease occurred in substantial numbers; the results suggest that unless other individual compelling contraindications are present, early initiation of ART near the time of initiating OI treatment should be considered for most patients with an acute OI, excluding TB. Other elements that should be considered when making this decision are degree of immunosuppression, availability of effective therapy for the OI, risk for drug interactions, overlapping drug toxicities, risk for the consequences of the development of IRIS, and

willingness of the patients to adhere to their drug regimens. In cases of cryptosporidiosis, microsporidiosis, PML, KS, PCP, and invasive bacterial infections, the early benefits of ART outweigh increased risk related to these other factors and ART should be started as soon as possible. In the setting of TB disease, awaiting a response to OI therapy might be warranted before initiating ART.

Management of Acute OIs in Patients Receiving ART

OIs that occur after patients have been started on ART can be categorized into three groups. The first group includes OIs that occur shortly after initiating ART (within 12 weeks). These cases might be subclinical infections that have been unmasked by early immune reconstitution or simply OIs that occurred because of advanced immunosuppression and are not considered to represent early failure of ART. Many of these cases represent IRIS *(54,56,69–72)*.

The second group includes OIs that occur >12 weeks after initiation of ART among patients with suppressed HIV ribonucleic acid (RNA) levels and sustained $CD4^+$ counts >200 cells/μL (*73,74*). Determining whether these represent a form of IRIS rather than incomplete immunity with the occurrence of a new OI is difficult. The third group includes OIs that occur among patients who are experiencing virologic and immunologic failure while on ART. These represent clinical failure of ART.

When an OI occurs within 12 weeks of starting ART, treatment for the OI should be started and ART should be continued. When an OI occurs despite complete virologic suppression (i.e., late OI), therapy for the OI should be initiated and ART should be continued. If the $CD4^+$ response to ART has been suboptimal, modification of the ART regimen may be considered, although no evidence exists to indicate that changing the ART regimen in this setting will improve the $CD4^+$ response. When an OI occurs in the setting of virologic failure, OI therapy should be started, antiretroviral resistance testing should be performed, and the ART regimen should be modified, if possible, to achieve better virologic control.

Special Considerations During Pregnancy

No large studies have been conducted concerning the epidemiology or manifestations of HIV-associated OIs among pregnant women. No data demonstrate that the spectrum of OIs differs from that among nonpregnant women with comparable $CD4^+$ counts.

Physiologic changes during pregnancy can complicate the recognition of OIs and complicate pharmacokinetics. Factors to consider include the following (*75*):

- Increased cardiac output by 30%–50% with concomitant increase in glomerular filtration rate and renal clearance.
- Increased plasma volume by 45%–50% while red cell mass increases only by 20%–30%, leading to dilutional anemia.
- Tidal volume and pulmonary blood flow increase, possibly leading to increased absorption of aerosolized medications. The tidal volume increase of 30%–40% should be considered if ventilatory assistance is required.
- Placental transfer of drugs, increased renal clearance, altered gastrointestinal absorption, and metabolism by the fetus might affect maternal drug levels.
- Limited pharmacokinetic data are available; use usual adult doses based on current weight, monitor levels if available, and consider the need to increase doses if the patient is not responding as expected.

Fetal risk is not increased with cumulative radiation doses below 5 rads; the majority of imaging studies result in radiation exposure to the fetus that is lower than the 5-rad recommended limit. In humans, the primary risks associated with high-dose radiation exposure are growth restriction, microcephaly, and developmental disabilities. The most vulnerable period is 8–15 menstrual weeks of gestation with minimal risk before 8 weeks and after 25 weeks. The apparent threshold for development of mental retardation is 20–40 rads, with risk of more serious mental retardation increasing linearly with increasing exposures above this level. Among children, risk for carcinogenesis might be increased approximately 1 per 1,000 or less per rad of in utero radiation exposure (*76*). Therefore, pregnancy should not preclude usual diagnostic evaluation when an OI is suspected (*76–78*). Abdominal shielding should be used when feasible to further limit radiation exposure to the fetus. Experience with use of magnetic resonance imaging (MRI) in pregnancy is limited, but no adverse fetal effects have been noted (*76*).

Other procedures necessary for diagnosis of suspected OIs should be performed in pregnancy as indicated for nonpregnant patients. A pregnant women who is >20 weeks of gestation should not lie flat on her back but should have her left hip elevated with a wedge to displace the uterus off the great vessels and prevent supine hypotension. Oxygenation should be monitored when pregnant patients are positioned such that ventilation or perfusion might be compromised.

For pregnant women who have had an OI diagnosed and are not on ART, immediate initiation of ART with OI therapy should be encouraged to minimize the risk for perinatal transmission of HIV (*79*). Decisions about immediate versus delayed initiation of ART in pregnancy should include con-

sideration of gestational age, maternal HIV RNA levels and clinical condition, and potential toxicities and interactions between ART and OI drugs.

After first-trimester exposure to agents of uncertain teratogenic potential, a detailed ultrasound examination at 18–20 weeks should be conducted to detect possible major anomalies. For women who receive drugs that have not been extensively evaluated during pregnancy, an ultrasound should be conducted every 4–6 weeks to assess fetal growth and fluid volume, with antepartum testing if growth lag or decreased fluid are noted. Women in the third trimester of pregnancy should be instructed in daily fetal movement counting to detect decreased activity that might indicate fetal compromise (*80*).

Disease Specific Recommendations

Pneumocystis Pneumonia

Epidemiology

Pneumocystis pneumonia (PCP) is caused by *Pneumocystis jirovecii,* a ubiquitous organism that is classified as a fungus but that also shares biologic characteristics with protozoa. The taxonomy of the organism has been changed; *Pneumocystis carinii* now refers only to the pneumocystis that infects rodents, and *Pneumocystis jirovecii* refers to the distinct species that infects humans. The abbreviation PCP is still used to designate *Pneumocystis* pneumonia. Initial infection with *P. jirovecii* usually occurs in early childhood; two thirds of healthy children have antibody to *P. jirovecii* by age 2–4 years (*81*). Rodent studies and case clusters among immunosuppressed patients suggest that *Pneumocystis* spreads by the airborne route. Disease probably occurs by new acquisition of infection and by reactivation of latent infection (*82–84*). Before the widespread use of primary PCP prophylaxis and ART, PCP occurred in 70%–80% of patients with AIDS (*85*); the course of treated PCP was associated with a mortality of 20%–40% in persons with profound immunosuppression. Approximately 90% of cases occurred among patients with $CD4^+$ counts of <200 cells/μL. Other factors associated with a higher risk for PCP included $CD4^+$ cell percentage <14%, previous episodes of PCP, oral thrush, recurrent bacterial pneumonia, unintentional weight loss, and higher plasma HIV RNA (*86,87*).

Incidence of PCP has declined substantially with widespread use of prophylaxis and ART; recent incidence among patients with AIDS in Western Europe and the United States is 2–3 cases per 100 person-years (*88*). The majority of cases occur among patients who are unaware of their HIV infection or are not receiving ongoing HIV care (*89*) or among those with advanced immunosuppression ($CD4^+$ counts <100 cells/μL) (*90*).

Clinical Manifestations

The most common manifestations of PCP among HIV-infected persons are the subacute onset of progressive dyspnea, fever, nonproductive cough, and chest discomfort that worsens within days to weeks. The fulminant pneumonia observed among non-HIV-infected patients is less common (*91,92*).

In mild cases, pulmonary examination is usually normal at rest. With exertion, tachypnea, tachycardia, and diffuse dry ("cellophane") rales might be observed (*92*). Oral thrush is a common coinfection. Fever is apparent in the majority of cases and might be the predominant symptom among some patients. Extrapulmonary disease is rare but can occur in any organ and has been associated with use of aerosolized pentamidine prophylaxis.

Hypoxemia, the most characteristic laboratory abnormality, might range from mild (room air arterial oxygen [pO2] of $\geq$70 mm Hg or alveolar-arterial O2 difference, [A-a] DO2 <35 mm Hg) to moderate ([A-a] DO2 >35 and <45 mm Hg) to severe levels ([A-a] DO2 >45 mm Hg). Oxygen desaturation with exercise is indicative of an abnormal A-a gradient but is nonspecific (*93*). Elevation of lactate dehydrogenase levels to >500 mg/dL is common but nonspecific (*94*). The chest radiograph typically demonstrates diffuse, bilateral, symmetrical interstitial infiltrates emanating from the hila in a butterfly pattern (*92*); however, patients with early disease might have a normal chest radiograph (*95*). In addition, atypical presentations with nodules, blebs and cysts, asymmetric disease, upper lobe localization, and pneumothorax occur. Pneumothorax in a patient with HIV infection should raise the suspicion of PCP (*96,97*). Cavitation, intrathoracic adenopathy, and pleural effusion are uncommon in the absence of other pulmonary pathogens or malignancy, and their presence might indicate an alternative diagnosis. Approximately 13%–18% of patients with documented PCP have another concurrent cause of pulmonary dysfunction (e.g., TB, KS, or bacterial pneumonia) (*98,99*).

Thin-section computerized tomography (CT) demonstrating patchy ground-glass attenuation (*100,101*) or a gallium scan indicating increased pulmonary uptake *(102*) increases the likelihood that a diagnostic study such as bronchoscopy would demonstrate PCP in patients with mild-to-moderate symptoms and a normal chest radiograph and might be useful as adjunctive studies.

Diagnosis

Because the clinical presentation, blood tests, or chest radiographs are not pathognomonic for PCP and the organism cannot be cultivated routinely, histopathologic demonstration of organisms in tissue, bronchoalveolar lavage fluid, or induced sputum samples (*98,99,103,104*) are required for a

definitive diagnosis. Spontaneously expectorated sputum has low sensitivity and should not be submitted to the laboratory to diagnose PCP. Giemsa, Diff-Quik, and Wright stains detect both the cyst and trophozoite forms but do not stain the cyst wall; Gomori methenamine silver, Gram-Weigert, cresyl violet, and toluidine blue stain the cyst wall. Certain laboratories prefer direct immunofluorescent staining. Nucleic acid tests have greater sensitivity but less specificity than colorimetric or immunologic stains and can be combined with noninvasive samples such as induced sputum or oral wash samples; however, their availability is limited (*105–107*). (1→3)ß-D-glucan (a component of fungal cell walls) might be elevated in patients with PCP, but the sensitivity and specificity of this assay to establish a diagnosis of PCP has not been adequately evaluated. (*108*).

Previous studies of stained respiratory tract samples obtained by various methods indicate the following relative diagnostic sensitivities: induced sputum <50%–>90% (the sensitivity and specificity depend on the quality of the specimens and the experience of the microbiologist or pathologist), bronchoscopy with bronchoalveolar lavage 90%–99%, transbronchial biopsy 95%–100%, and open lung biopsy 95%–100%.

Because of the potential for certain processes to have similar clinical manifestations, a specific diagnosis of PCP should be sought rather than relying on a presumptive diagnosis, especially in patients with moderate-to-severe disease. Treatment can be initiated before making a definitive diagnosis because organisms persist in clinical specimens for days or weeks after effective therapy is initiated (*104*).

Preventing Exposure

Certain authorities might recommend that persons who are at risk for PCP not share a hospital room with a patient who has PCP, a recommendations based on animal studies and anecdotal human experience. Data are insufficient to support this recommendation as standard practice **(CIII)**.

Preventing Disease

Initiating Primary Prophylaxis

HIV-infected adults and adolescents, including pregnant women and those on ART, should receive chemoprophylaxis against PCP if they have a $CD4^+$ count of <200 cells/μL **(AI)** or a history of oropharyngeal candidiasis **(AII)** (*32,85,86*). Persons who have a $CD4^+$ cell percentage of <14% or a history of an AIDS-defining illness, but do not otherwise qualify, should be considered for prophylaxis **(BII)** (*32,85,86*). When monitoring $CD4^+$ counts frequently (e.g., every 1–3 months) is not possible, initiating chemoprophylaxis at a $CD4^+$ count of >200, but <250 cells/μL, also should be considered **(BII)** (*86*).

TMP-SMX is the recommended prophylactic agent **(AI)** (*32,109–111*). One double-strength tablet daily is the preferred regimen **(AI)**. However, one single-strength tablet daily (*111*) also is effective and might be better tolerated than one double-strength tablet daily **(AI)**. One double-strength tablet three times weekly also is effective **(BI)** (*112*). TMP-SMX at a dose of one double-strength tablet daily confers cross-protection against toxoplasmosis (*113*) and selected common respiratory bacterial infections (*109,114*). Lower doses of TMP-SMX also likely confer such protection. For patients who have an adverse reaction that is not life threatening, chemoprophylaxis with TMP-SMX should be continued if clinically feasible; for those who have discontinued such therapy because of an adverse reaction, reinstituting TMP-SMX should be strongly considered after the adverse event has resolved **(AII)**. Patients who have experienced adverse events, including fever and rash, might better tolerate reintroduction of the drug with a gradual increase in dose (i.e., desensitization), according to published regimens **(BI)** (*115,116*) or reintroduction of TMP-SMX at a reduced dose or frequency **(CIII)**; as many as 70% of patients can tolerate such reinstitution of therapy (*114*).

If TMP-SMX cannot be tolerated, alternative prophylactic regimens include dapsone **(BI)** (*109*), dapsone plus pyrimethamine plus leucovorin **(BI)** (*117–119*), aerosolized pentamidine administered by the Respirgard II nebulizer (manufactured by Marquest, Englewood, Colorado) **(BI)** (*110*), and atovaquone **(BI)** (*120,121*). Atovaquone is as effective as aerosolized pentamidine (*120*) or dapsone **(BI)** (*121*) but is substantially more expensive than the other regimens. For patients seropositive for *Toxoplasma gondii* who cannot tolerate TMP-SMX, recommended alternatives to TMP-SMX for prophylaxis against both PCP and toxoplasmosis include dapsone plus pyrimethamine plus leucovorin **(BI)** (*117–119*) or atovaquone with or without pyrimethamine plus leucovorin **(CIII)**.

Oral pyrimethamine plus sulfadoxine also has activity in preventing PCP **(CIII)** (*122–124*). This combination should not be used in patients with hypersensitivity to sulfonamides. Pyrimethamine plus sulfadoxine has an increased risk for severe cutaneous reactions, including Stevens-Johnson syndrome (*125*), and the long half-life of both pyrimethamine and sulfadoxine will result in a delayed clearance when the drug is stopped. Largely because TMP-SMX has superior safety, widespread availability, and is low cost, oral pyrimethamine plus sulfadoxine should be used rarely in the United States **(CIII)**.

The following regimens cannot be recommended as alternatives because data regarding their efficacy for PCP prophylaxis are insufficient:

- Aerosolized pentamidine administered by other nebulization devices
- Intermittently administered parenteral pentamidine
- Oral clindamycin plus primaquine.

However, clinicians might consider using these agents in unusual situations in which the recommended agents cannot be administered **(CIII)**.

Discontinuing Primary Prophylaxis

Primary pneumocystis prophylaxis should be discontinued for adult and adolescent patients who have responded to ART with an increase in CD4+ counts to >200 cells/μL for >3 months **(AI)**. In observational and randomized studies supporting this recommendation, the majority of patients were taking antiretroviral regimens that included a protease inhibitor (PI), and the majority had a CD4+ count of >200 cells/μL for >3 months before discontinuing PCP prophylaxis (88,126–134). The median CD4+ count at the time prophylaxis was discontinued was >300 cells/μL, most had a CD4+ cell percentage of ≥14 %, and many patients had a sustained suppression of HIV plasma RNA levels below detection limits of the assay employed. Median follow-up was 6–19 months.

Discontinuing primary prophylaxis among these patients is recommended because prophylaxis adds limited disease prevention (i.e., for PCP, toxoplasmosis, or bacterial infections) (*127,133*) and because discontinuing drugs reduces pill burden, potential for drug toxicity, drug interactions, selection of drug-resistant pathogens, and cost.

Prophylaxis should be reintroduced if the $CD4^+$ count decreases to <200 cells/μL **(AIII)**.

Treatment of Disease

TMP-SMX is the treatment of choice **(AI)** (*135,136*)**.** The dose must be adjusted for abnormal renal function. Multiple randomized clinical trials indicate that TMP-SMX is as effective as parenteral pentamidine and more effective than other regimens. Adding leucovorin to prevent myelosuppression during acute treatment is not recommended because of questionable efficacy and some evidence for a higher failure rate **(DII)** (*137*)**.** Oral outpatient therapy of TMP-SMX is highly effective among patients with mild-to-moderate disease **(AI)** (*136*)**.**

Mutations associated with resistance to sulfa drugs have been documented, but their effect on clinical outcome is uncertain (*138–140*). Patients who have PCP despite TMP-SMX prophylaxis are usually effectively treated with standard doses of TMP-SMX **(BIII)**.

Patients with documented or suspected PCP and moderate-to-severe disease, as defined by room air pO_2 <70 mm Hg or arterial-alveolar O_2 gradient >35 mm Hg, should receive adjunctive corticosteroids as early as possible, and certainly within 72 hours after starting specific PCP therapy **(AI)** (*141–146*). If steroids are started at a later time, their benefits are unclear, although the majority of clinicians would use them in such circumstances for patients with moderate-to-severe disease **(BIII)**. Methylprednisolone at 75% of the respective prednisone dose can be used if parenteral administration is necessary.

Alternative therapeutic regimens for mild-to-moderate disease include 1) dapsone and TMP **(BI)** (*136,147*) (this regimen might have similar efficacy and fewer side effects than TMP-SMX but is less convenient because of the number of pills), 2) primaquine plus clindamycin **(BI)** (*148–150*) (the clindamycin component can be administered intravenously for more severe cases; however, primaquine is only available orally), and 3) atovaquone suspension **(BI)** (*135,151*) (this is less effective than TMP-SMX for mild-to-moderate disease but has fewer side effects). Patients should be tested for G6PD deficiency whenever possible before administration of primaquine. Alternative therapeutic regimens for patients with moderate-to-severe disease include clindamycin-primaquine or intravenous (IV) pentamidine **(AI)** (*150,152,153*) (usually the drug of second choice for severe disease). Certain clinicians prefer IV pentamidine because of convincing data regarding its high degree of efficacy. Other clinicians prefer clindamycin-primaquine because this combination is better tolerated than pentamidine, although data regarding efficacy are not as robust as the data supporting pentamidine. Aerosolized pentamidine should not be used for the treatment of PCP because of limited efficacy and more frequent relapse **(DI)** (*152,154,155*). Trimetrexate is no longer available commercially.

The recommended duration of therapy for PCP is 21 days **(AII)** (*91*)**.** The probability and rate of response to therapy depend on the agent used, number of previous PCP episodes, severity of illness, degree of immunodeficiency, and timing of initiation of therapy.

Although the overall prognosis of patients whose degree of hypoxemia requires intensive care unit (ICU) admission or mechanical ventilation remains poor, survival in up to 50% of patients requiring ventilatory support has been reported in recent years (*156–158*). Because long-term survival is possible for patients in whom ART is effective, certain patients with AIDS and severe PCP should be offered intensive care unit (ICU) admission or mechanical ventilation when appropriate (e.g., when they have reasonable functional status) **(AII)**.

Because of the potential for additive or synergistic toxicities associated with anti-PCP and antiretroviral therapies, certain health-care providers delay initiation of ART until after the completion of anti-PCP therapy, or until at least 2 weeks after initiating anti-PCP therapy, despite some suggestion of

potential benefit of early ART in the treatment of PCP **(CIII)** (*157,159*).

Monitoring and Adverse Events, Including Immune Reconstitution Inflammatory Syndrome (IRIS)

Careful monitoring during therapy is important to evaluate response to treatment and to detect toxicity as soon as possible. Follow-up after therapy includes assessment for early relapse, especially when therapy has been with an agent other than TMP-SMX or was shortened for toxicity. PCP prophylaxis should be initiated immediately upon completion of therapy and maintained until the $CD4^+$ count is >200 cells/μL.

Adverse reaction rates among patients with AIDS are high for TMP-SMX (20%–85%) (*135,136,147,149,153,161–165*). Common adverse effects are rash (30%–55%) (including Stevens-Johnson syndrome), fever (30%–40%), leukopenia (30%–40%), thrombocytopenia (15%), azotemia (1%–5%), hepatitis (20%), and hyperkalemia. Supportive care for common adverse effects should be attempted before discontinuing TMP-SMX **(AIII)**. Rashes can often be "treated through" with antihistamines, nausea can be controlled with antiemetics, and fever can be managed with antipyretics.

The most common adverse effects of alternative therapies include methemoglobinemia and hemolysis with dapsone or primaquine (especially in those with G6PD deficiency); rash and fever with dapsone (*136,147*); azotemia, pancreatitis, hypo- or hyperglycemia, leukopenia, electrolyte abnormalities, and cardiac dysrhythmia with pentamidine (*151–153,164*); anemia, rash, fever, and diarrhea with primaquine and clindamycin (*136,148,149*); and headache, nausea, diarrhea, rash, and transaminase elevations with atovaquone (*135,163*).

IRIS has been reported following PCP. Most cases have occurred within weeks of the episode of PCP. Reported cases are not sufficient to provide guidance on the optimal time to start ART following a mild or severe case of PCP (*160,166*).

Management of Treatment Failure

Clinical failure is defined as lack of improvement or worsening of respiratory function documented by arterial blood gases (ABGs) after at least 4–8 days of anti-PCP treatment. Treatment failure attributed to treatment-limiting toxicities occurs in up to one third of patients (*136*). Switching to another regimen is the appropriate management for treatment-related toxicity **(BII)**. Failure attributed to lack of drug efficacy occurs in approximately 10% of those with mild-to-moderate disease. No convincing clinical trials exist on which to base recommendations for the management of treatment failure attributed to lack of drug efficacy. Clinicians should wait at least 4–8 days before switching therapy for lack of clinical improvement **(BIII)**. In the absence of corticosteroid therapy, early and reversible deterioration within the first 3–5 days of therapy is typical, probably because of the inflammatory response caused by antibiotic-induced lysis of organisms in the lung. Other concomitant infections must be excluded as a cause for clinical failure (*98,99*); bronchoscopy with bronchoalveolar lavage should be strongly considered to evaluate for this possibility, even if it was conducted before initiating therapy.

If TMP-SMX has failed or must be avoided for toxicity in moderate-to-severe disease, the common practice is to use parenteral pentamidine or primaquine combined with clindamycin **(BII)** (*149,153,165*). As noted above, trimetrexate is no longer available commercially. For mild disease, atovaquone is a reasonable alternative **(BII)**. Although one meta-analysis concluded that the combination of clindamycin and primaquine might be the most effective regimen for salvage therapy (*150*), no prospective clinical trials have evaluated the optimal approach to patients who experience a therapy failure with TMP-SMX.

Preventing Recurrence

Patients who have a history of PCP should be administered chemoprophylaxis for life (i.e., secondary prophylaxis or chronic maintenance therapy) with TMP-SMX unless immune reconstitution occurs as a result of ART (*167*) **(AI)**. For patients who are intolerant of TMP-SMX, alternatives are dapsone, dapsone combined with pyrimethamine, atovaquone, or aerosolized pentamidine.

Discontinuing Secondary Prophylaxis (Chronic Maintenance Therapy)

Secondary prophylaxis should be discontinued for adult and adolescent patients whose $CD4^+$ count has increased from <200 cells/μL to >200 cells/μL for >3 months as a result of ART **(BII)**. Reports from observational studies (*126,132,168,169*) and from two randomized trials (*133,170*) and a combined analysis of eight European cohorts being followed prospectively (*171*) support this recommendation. In these studies, patients had responded to ART with an increase in $CD4^+$ counts to $\geq$200 cells/μL for >3 months. The majority of patients were taking PI-containing regimens. The median $CD4^+$ count at the time prophylaxis was discontinued was >300 cells/μL and most had a $CD4^+$ cell percentage of >14%. The majority of patients had sustained suppression of plasma HIV RNA levels below the detection limits of the assay employed; the longest follow-up was 40 months. If the episode of PCP occurred at a $CD4^+$ count of >200 cells/μL, continuing PCP prophylaxis for life, regardless of how high the $CD4^+$ count rises as a consequence of ART, would be prudent **(CIII)**; however, data regarding the most appropriate approach in this setting are limited.

Discontinuing secondary prophylaxis for patients is recommended because prophylaxis adds limited disease prevention (i.e., for PCP, toxoplasmosis, or bacterial infections) and because discontinuing drugs reduces pill burden, potential for drug toxicity, drug interactions, selection of drug-resistant pathogens, and cost.

Prophylaxis should be reintroduced if the CD4+ count decreases to <200 cells/μL **(AIII)**. If PCP recurs at a CD4+ count of ≥200 cells/μL, lifelong prophylaxis should be administered **(CIII)**.

Special Considerations During Pregnancy

PCP diagnostic considerations for pregnant women are the same as for nonpregnant women. Indications for therapy are the same as for nonpregnant women. The preferred initial therapy during pregnancy is TMP-SMX, although alternate therapies can be used if patients are unable to tolerate or are unresponsive to TMP-SMX (*172*) **(AI)**. In case-control studies, trimethoprim has been associated with an increased risk for neural tube defects and cardiovascular, urinary tract, and multiple anomalies after first-trimester exposure (*173–175*). Epidemiologic data suggest that folic acid supplementation might reduce this risk (*174,175*), but no controlled studies have been done. In a small study, an increased risk for birth defects among infants born to women receiving antiretrovirals and folate antagonists, primarily trimethoprim, was reported, whereas no increase was observed among those with either antiretroviral or folate antagonist exposure alone (*176*). Although first-trimester exposure to trimethoprim might be related to a small increased risk for birth defects, pregnant women in their first trimester with PCP should be treated with TMP-SMX **(AIII)**. Although folic acid supplementation of 0.4 mg/day is routinely recommended for all pregnant women (*177*), data do not indicate if higher levels of supplementation, such as the 4 mg/day recommended for pregnant women with a previous infant with a neural tube defect, would provide added benefit in this situation. Follow-up ultrasound to assess fetal anatomy at 18–20 weeks is recommended **(BIII)**.

Neonatal-care providers should be informed of maternal sulfa or dapsone therapy if used near the delivery date because of the theoretical increased risk for hyperbilirubinemia and kernicterus (*178*).

Pentamidine is embryotoxic but not teratogenic among rats and rabbits (*179*). Adjunctive corticosteroid therapy should be used as indicated in nonpregnant adults (*180–183*) **(AIII)**. Maternal fasting and postprandial glucose levels should be monitored closely when corticosteroids are used in the third trimester because the risk for glucose intolerance is increased.

Rates of preterm labor and preterm delivery are increased with pneumonia during pregnancy. Pregnant women with pneumonia after 20 weeks of gestation should be monitored for evidence of contractions **(BII)**.

Chemoprophylaxis for PCP should be administered to pregnant women the same as for other adults and adolescents **(AIII)**. TMP-SMX is the recommended prophylactic agent; dapsone is an alternative. Because of theoretical concerns regarding possible teratogenicity associated with drug exposures during the first trimester, health-care providers might withhold prophylaxis during the first trimester. In such cases, aerosolized pentamidine can be considered because of its lack of systemic absorption and the resultant lack of exposure of the developing embryo to the drug **(CIII)**.

Toxoplasma gondii Encephalitis

Toxoplasmic encephalitis (TE) is caused by the protozoan *Toxoplasma gondii*. Disease appears to occur almost exclusively because of reactivation of latent tissue cysts (*184–187*). Primary infection occasionally is associated with acute cerebral or disseminated disease.

Epidemiology

Seroprevalence varies substantially among different communities (e.g., approximately 15% in the United States and 50%–75% in certain European countries) (*187,188*). In the pre-ART era, for patients with advanced immunosuppression who were seropositive for *T. gondii* and not receiving prophylaxis with drugs active against *T. gondii*, the 12-month incidence of TE was approximately 33%. The incidence of toxoplasmosis in patients who are seronegative for *T. gondii* is low. If well-documented cases did occur among seronegative patients, they would presumably represent either primary infection, reactivation of latent disease in patients unable to produce detectable antibody, or patients who were tested with insensitive assays. The incidence and associated mortality in Europe and the United States have decreased substantially with the initiation of ART and the broad use of prophylaxis regimens active against *T. gondii (189,190)*.

Clinical disease is rare among patients with CD4+ counts >200 cells/μL. The greatest risk occurs among patients with a CD4+ count <50 cells/μL (*184–186,190*). Primary infection occurs after eating undercooked meat containing tissue cysts or ingesting oocysts that have been shed in cat feces and have sporulated in the environment (sporulation requires at least 24 hours). No transmission of the organism occurs by person-to-person contact.

Clinical Manifestations

The most common clinical presentation of *T. gondii* infection among patients with AIDS is focal encephalitis with headache, confusion, or motor weakness and fever (*184–186*). Physical

examination might demonstrate focal neurological abnormalities, and in the absence of treatment, disease progression results in seizures, stupor, and coma. Retinochoroiditis, pneumonia, and evidence of other multifocal organ system involvement can be observed after dissemination of infection but are rare manifestations in this patient population. CT scan or MRI of the brain will typically show multiple contrast-enhancing lesions, often with associated edema (*184,185,191–193*). However, toxoplasmosis also can manifest as single lesions in the brain.

Diagnosis

HIV-infected patients with TE are almost uniformly seropositive for anti-toxoplasma immunoglobulin G (IgG) antibodies (*184–186,194*). The absence of IgG antibody makes a diagnosis of toxoplasmosis unlikely but not impossible. Anti-toxoplasma immunoglobulin M (IgM) antibodies are usually absent. Quantitative antibody titers are not diagnostically useful.

Definitive diagnosis of TE requires a compatible clinical syndrome; identification of one or more mass lesions by CT, MRI, or other radiographic testing; and detection of the organism in a clinical sample. For TE, this requires a brain biopsy, which is most commonly performed by a stereotactic CT-guided needle biopsy. Organisms are demonstrable with hematoxylin and eosin stains, although immunoperoxidase staining by experienced laboratories might increase sensitivity (*195*). Detection of *T. gondii* by polymerase chain reaction (PCR) in cerebrospinal fluid (CSF) has produced disappointing results; although specificity is high (96%–100%), sensitivity is low (50%) and the results usually are negative once specific anti-toxoplasma therapy has been started (*196,197*).

The differential diagnosis of focal neurological disease in patients with AIDS includes central nervous system (CNS) lymphoma; mycobacterial infection (especially TB); fungal infection (e.g., cryptococcosis); Chagas disease; bacterial abscess; and rarely PML, which can be distinguished on the basis of imaging studies (PML lesions typically involve white matter rather than gray matter, are noncontrast enhancing, and produce no mass effect).

The majority of clinicians rely initially on an empiric diagnosis, which can be established as an objective response, on the basis of clinical and radiographic improvement, to specific anti-*T. gondii* therapy in the absence of a likely alternative diagnosis. Brain biopsy is reserved for patients who fail to respond to specific therapy. In patients with contrast-enhancing mass lesions, detection of Epstein-Barr virus (EBV) by PCR in CSF is highly suggestive of CNS lymphoma (*198,199*). Positron emission tomography (PET) (*192*) or single-photon emission computed tomography (SPECT) scanning (*193*) might be helpful for distinguishing between TE and primary CNS lymphoma, but no imaging technique is completely specific.

Preventing Exposure

HIV-infected persons should be tested for IgG antibody to *Toxoplasma* soon after the diagnosis of HIV infection to detect latent infection with *T. gondii* **(BIII)**.

HIV-infected persons, including those who lack IgG antibody to *Toxoplasma*, should be counseled regarding sources of *Toxoplasma* infection. To minimize risk for acquiring toxoplasmosis, HIV-infected persons should be advised not to eat raw or undercooked meat, including undercooked lamb, beef, pork, or venison **(BIII)**. Specifically, lamb, beef, venison, and pork should be cooked to an internal temperature of 165ºF–170ºF (*200*); meat cooked until it is no longer pink inside usually has an internal temperature of 165ºF–170ºF and therefore, from a more practical perspective, satisfies this requirement. To minimize the risk for acquiring toxoplasmosis, HIV-infected persons should wash their hands after contact with raw meat and after gardening or other contact with soil; in addition, they should wash fruits and vegetables well before eating them raw **(BIII)**. If the patient owns a cat, the litter box should be changed daily, preferably by an HIV-negative, nonpregnant person; alternatively, patients should wash their hands thoroughly after changing the litter box **(BIII)**. Patients should be encouraged to keep their cats inside and not to adopt or handle stray cats **(BIII)**. Cats should be fed only canned or dried commercial food or well-cooked table food, not raw or undercooked meats **(BIII)**. Patients need not be advised to part with their cats or to have their cats tested for toxoplasmosis **(EII)**.

Preventing Disease

Initiating Primary Prophylaxis

Toxoplasma-seropositive patients who have a $CD4^+$ count of <100 cells/μL should be administered prophylaxis against TE **(AII)** (*113*). The double-strength tablet daily dose of TMP-SMX recommended as the preferred regimen for PCP prophylaxis also is effective against TE and is therefore recommended **(AII)** (*113*). TMP-SMX, one double-strength tablet three times weekly, is an alternative **(BIII)**. If patients cannot tolerate TMP-SMX, the recommended alternative is dapsone-pyrimethamine plus leucovorin, which is also effective against PCP **(BI)** (*117–119*)**.** Atovaquone with or without pyrimethamine/leucovorin also can be considered **(CIII)**. Prophylactic monotherapy with dapsone, pyrimethamine, azithromycin, or clarithromycin cannot be recommended on the basis of available data **(DII)**. Aerosolized pentamidine does not protect against TE and is not recommended **(EI)** (*109,113*)**.**

Toxoplasma-seronegative persons who are not taking a PCP prophylactic regimen known to be active against TE (e.g., aerosolized pentamidine) should be retested for IgG antibody to *Toxoplasma* when their CD4+ counts decline to <100 cells/μL to determine whether they have seroconverted and are therefore at risk for TE **(CIII)**. Patients who have seroconverted should be administered prophylaxis for TE as described previously **(AII)**.

Discontinuing Primary Prophylaxis

Prophylaxis against TE should be discontinued among adult and adolescent patients who have responded to ART with an increase in CD4+ counts to >200 cells/μL for >3 months **(AI)**. Multiple observational studies (*126,132,201*) and two randomized trials (*127,202*) have reported that primary prophylaxis can be discontinued with minimal risk for developing TE among patients who have responded to ART with an increase in CD4+ count from <200 cells/μL to >200 cells/μL for >3 months. In these studies, the majority of patients were taking PI-containing regimens and the median CD4+ count at the time prophylaxis was discontinued was >300 cells/μL. At the time prophylaxis was discontinued, the majority of patients had sustained suppression of plasma HIV RNA levels below the detection limits of available assays; the median follow-up was 7–22 months. Although patients with CD4+ counts of <100 cells/μL are at greatest risk for having TE, the risk for TE occurring when the CD4+ count has increased to 100–200 cells/μL has not been studied as rigorously as an increase to >200 cells/μL. Thus, the recommendation specifies discontinuing prophylaxis after an increase to >200 cells/μL. Discontinuing primary TE prophylaxis is recommended because prophylaxis at CD4+ count >200 cells/ μL adds limited disease prevention for toxoplasmosis and because discontinuing drugs reduces pill burden, potential for drug toxicity, drug interaction, selection of drug-resistant pathogens, and cost. Prophylaxis for TE should be reintroduced if the CD4+ count decreases to <100–200 cells/μL **(AIII)**.

Treatment of Disease

The initial therapy of choice for TE consists of the combination of pyrimethamine plus sulfadiazine plus leucovorin **(AI)** (*203–206*)**.** Pyrimethamine penetrates the brain parenchyma efficiently even in the absence of inflammation (*207*). Use of leucovorin reduces the likelihood of the hematologic toxicities associated with pyrimethamine therapy (*208,209*). The preferred alternative regimen for patients with TE who are unable to tolerate or who fail to respond to first-line therapy is pyrimethamine plus clindamycin plus leucovorin **(AI)** (*203,204*)**.**

TMP-SMX was reported in a small (77 patients) randomized trial to be effective and better tolerated than pyrimethamine-sulfadiazine (*210*). On the basis of less in vitro activity and less experience with TMP-SMX, treatment with this drug may be considered an option **(BI)**. For patients who cannot take an oral regimen, no well-studied options exist. No parenteral formulation of pyrimethamine exists; the only widely available parenteral sulfonamide is the sulfamethoxazole component of TMP-SMX. Certain specialists will treat severely ill patients initially requiring parenteral therapy for TE with parenteral TMP-SMX or oral pyrimethamine plus parenteral clindamycin **(CIII)**.

The following regimens have been show to be effective in the treatment of TE in at least two nonrandomized, uncontrolled trials, although their relative efficacy compared with the previous regimens is unknown: atovaquone (with meals or oral nutritional supplements) plus either pyrimethamine plus leucovorin or sulfadiazine or, for patients intolerant of both pyrimethamine and sulfadiazine, as a single agent **(BII)** (*211–214*) (if atovaquone is used alone, clinicians should be aware that different patients experience a high variability of absorption of the drug; plasma levels of >18.5 μg/mL are associated with an improved response rate but measurements are not routinely available) (*212–214*); and azithromycin plus pyrimethamine plus leucovorin daily **(BII)** (*215,216*).

The following regimens have been reported to have activity in the treatment of TE in small cohorts of patients or in case reports of one or several patients: clarithromycin plus pyrimethamine **(CIII)** (*217*); 5-fluorouracil plus clindamycin **(CIII)** (*218*), dapsone plus pyrimethamine plus leucovorin **(CIII)** (*219*); and minocycline or doxycycline combined with either pyrimethamine plus leucovorin, sulfadiazine, or clarithromycin **(CIII)** (*220,221*). Although the clarithromycin dose used in the only published study was 1g twice a day, doses >500 mg have been associated with increased mortality in HIV-infected patients treated for disseminated MAC. Doses >500 mg twice a day should not be used **(DIII)**.

Acute therapy for TE should be continued for at least 6 weeks, if there is clinical and radiologic improvement **(BII)** (*184–187*). Longer courses might be appropriate if clinical or radiologic disease is extensive or response is incomplete at 6 weeks. CNS lesions must not have contrast enhancement on CT/MRI. Adjunctive corticosteroids (e.g., dexamethasone) should be administered to patients with TE when clinically indicated only for treatment of a mass effect associated with focal lesions or associated edema **(BIII)**. Because of the potential immunosuppressive effects of corticosteroids, they should be discontinued as soon as clinically feasible. Patients receiving corticosteroids should be monitored closely for the

development of other OIs, including cytomegalovirus (CMV) retinitis and TB disease.

Anticonvulsants should be administered to patients with TE who have a history of seizures **(AIII)**, but should not be administered as prophylactics to all patients **(DIII)**. Anticonvulsants, if administered, should be continued at least through the period of acute therapy.

Monitoring and Adverse Events, Including Immune Reconstitution Inflammatory Syndrome (IRIS)

Changes in antibody titers are not useful for monitoring responses to therapy. Patients with TE should be monitored routinely for adverse events and clinical and radiologic improvement **(AIII)**. Common pyrimethamine toxicities include rash, nausea, and bone marrow suppression (neutropenia, anemia, and thrombocytopenia) that can often be reversed by increasing the dose of leucovorin to 50–100 mg/day administered in divided doses **(CIII)**.

Common sulfadiazine toxicities include rash, fever, leukopenia, hepatitis, nausea, vomiting, diarrhea, and crystalluria. Common clindamycin toxicities include fever, rash, nausea, diarrhea (including pseudomembranous colitis or diarrhea related to *Clostridium difficile* toxin), and hepatotoxicity. Common TMP-SMX toxicities include rash, fever, leukopenia, thrombocytopenia, and hepatotoxicity. Drug interactions between anticonvulsants and antiretroviral agents should be evaluated carefully and doses adjusted according to established guidelines.

Several cases of neurologic disease have been attributed to immune reconstitution and toxoplasmosis, but more data are needed to verify that such cases are IRIS related to *T. gondii* (*222*).

Management of Treatment Failure

A brain biopsy, if not previously performed, should be strongly considered for patients who fail to respond to initial therapy for TE **(BII)** as defined by clinical or radiologic deterioration during the first week despite adequate therapy or lack of clinical improvement within 2 weeks. For those who undergo brain biopsy and have confirmed histopathologic evidence of TE, a switch to an alternative regimen as previously described should be considered **(BIII)**. Recurrence of disease during secondary maintenance therapy following an initial clinical and radiographic response is unusual if patients adhere to their regimens.

Preventing Recurrence

Patients who have completed initial therapy for TE should be administered lifelong suppressive therapy (i.e., secondary prophylaxis or chronic maintenance therapy) **(AI)** (*203,204*) unless immune reconstitution occurs as a consequence of ART, in which case discontinuation of treatment is indicated. The combination of pyrimethamine plus sulfadiazine plus leucovorin is highly effective as suppressive therapy for patients with TE **(AI)** and provides protection against PCP **(AII)**. Although sulfadiazine is routinely dosed as a four times a day regimen, a pharmacokinetic study suggests bioequivalence when using the same total daily dose in a twice a day or four times a day regimen (*223*), and limited clinical experience suggests that twice a day dosing is effective (*224*). A commonly used regimen as suppressive therapy for patients with TE who cannot tolerate sulfa drugs is pyrimethamine plus clindamycin **(BI)**. Because of the high failure rate observed with lower doses (*203*), a dose of 600 mg clindamycin every 8 hours is recommended **(CIII)**. However, this regimen does not provide protection against PCP **(AII)**, and thus an additional agent (e.g., aerosol pentamidine) must be used. Atovaquone with or without pyrimethamine or sulfadiazine is also active against both TE and PCP **(BII)** but is substantially more expensive (*121*). A small uncontrolled study in patients who had been receiving ART for a median of 13 months suggested that TMP-SMX could be used as a suppressive regimen to reduce pill burden (*225*).

Discontinuing Secondary Prophylaxis (Chronic Maintenance Therapy)

Adult and adolescent patients receiving secondary prophylaxis (i.e., chronic maintenance therapy) for TE are at low risk for recurrence of TE when they have successfully completed initial therapy for TE, remain asymptomatic with regard to signs and symptoms of TE, and have a sustained increase in their $CD4^+$ counts of >200 cells/μL after ART (e.g., >6 months) (*132,168,202,226*). Although the numbers of patients who have been evaluated in observational studies and in one randomized clinical trial remain limited, and occasional recurrences have been reported, on the basis of these observations and inference from more extensive cumulative data indicating the safety of discontinuing secondary prophylaxis for other OIs during advanced HIV disease, discontinuing chronic maintenance therapy among such patients is a reasonable consideration **(BI)**. Certain specialists recommend obtaining an MRI of the brain as part of their evaluation to determine whether discontinuing therapy is appropriate by assessing whether the brain lesions had resolved.

Secondary prophylaxis (chronic maintenance therapy) for TE should be reintroduced if the $CD4^+$ count decreases to <200 cells/μL **(AIII)**.

Special Considerations During Pregnancy

Documentation of maternal *T. gondii* serologic status should be obtained during pregnancy. Indications for treatment of *T. gondii* during pregnancy should be based on confirmed or

suspected symptomatic disease in the mother. Pediatric-care providers should be informed if the HIV-infected mother is seropositive for *T. gondii* infection to allow evaluation of the neonate for evidence of congenital infection. Pregnant HIV-infected women with suspected or confirmed primary *T. gondii* infection during pregnancy should be managed in consultation with a maternal-fetal medicine or other appropriate specialist **(BIII)** (*227*)**.**

Treatment should be the same as in nonpregnant adults (**BIII**). Although pyrimethamine has been associated with birth defects in animals, limited human data have not suggested an increased risk for defects and, therefore, it can be administered to pregnant women (*228–230*). Pediatric providers should be notified if sulfadiazine is continued until delivery because its use might increase the risk for neonatal hyperbilirubinemia and kernicterus *(230*).

Although perinatal transmission of *T. gondii* normally occurs only with acute infection in the immunocompetent host, case reports have documented occurrences of transmission with reactivation of chronic infection in HIV-infected women with severe immunosuppression (*229,231*). Pregnant, HIV-infected women who have evidence of primary toxoplasmic infection or active toxoplasmosis, including TE, should be evaluated and managed during pregnancy in consultation with appropriate specialists **(BIII)**. Because the risk for transmission with chronic infection appears low, routine evaluation of the fetus for infection with amniocentesis or cordocentesis is not indicated. Detailed ultrasound examination of the fetus specifically evaluating for hydrocephalus, cerebral calcifications, and growth restriction should be done for HIV-infected women with suspected primary or symptomatic reactivation of *T. gondii* during pregnancy.

TMP-SMX can be administered for primary prophylaxis against TE as described for PCP **(AIII)**. Secondary prophylaxis should be provided using the same indications as for nonpregnant women. The risks of TMP-SMX in the first trimester, as discussed for PCP, must be balanced against the risk for recurrent TE.

Cryptosporidiosis

Epidemiology

Cryptosporidiosis is caused by various species of the protozoan parasite *Cryptosporidium*, which infect the small bowel mucosa, and in immunosuppressed persons, the large bowel and extra-intestinal sites. Persons at greatest risk for disease have advanced immunosuppression, typically $CD4^+$ counts of <100 cells/μL (*232*). The three most common species infecting humans are *C. hominis*, *C. parvum*, and *C. meleagridis*. Infections are usually caused by one species but might be mixed (*233*).

In developed countries with low rates of environmental contamination where potent ART is widely available, cryptosporidiosis occurs at an incidence of <1 per 100 person-years among persons with AIDS. Infection occurs through ingestion of *Cryptosporidium* oocysts. Viable oocysts in feces can be transmitted directly through contact with infected humans or animals, particularly those with diarrhea. Oocysts can contaminate recreational water sources (e.g., swimming pools, lakes) and public water supplies and might persist despite standard chlorination (see Appendix: Food and Water-Related Exposures). Person-to-person transmission is common, especially among sexually active men who have sex with men (MSM). Young children with cryptosporidial diarrhea might infect adults during diapering and cleaning after defecation.

Clinical Manifestations

Patients with cryptosporidiosis most commonly have acute or subacute onset of profuse, nonbloody, watery diarrhea, accompanied often by nausea, vomiting, and lower abdominal cramping (*234*). Fever is present in approximately one third of patients and malabsorption is common. The epithelium of the biliary tract and the pancreatic duct can be infected with *Cryptosporidium,* leading to sclerosing cholangitis and to pancreatitis secondary to papillary stenosis, particularly among patients with prolonged disease and low $CD4^+$ counts (*235–238*). Pulmonary infections also have been reported (*239,240*).

Diagnosis

Cryptosporidium species can be cultivated in vitro, but not as a routine diagnostic procedure. Diagnosis of cryptosporidiosis can be made by microscopic identification of the oocysts in stool or tissue. Acid-fast staining methods, with or without stool concentration, are most frequently used in clinical laboratories. Oocysts stain varying intensities of red with a modified acid-fast technique, permitting their differentiation from yeasts, which are of similar size and shape but are not acid fast. *Cryptosporidium* oocysts also can be detected by direct immunofluorescence, which offers the greatest sensitivity and specificity, or by enzyme-linked immunosorbent assays (ELISAs) (*241*). Molecular methods such as PCR are predicted to enhance sensitivity further. Cryptosporidial enteritis also can be diagnosed from small intestinal biopsy sections. The organism, which appears basophilic with hematoxylin and eosin staining, occurs alone or in clusters in various developmental stages on the brush border of the mucosal epithelial surfaces.

Among persons with profuse diarrheal illness, a single stool specimen is usually adequate for diagnosis. Among persons

with milder disease, repeat stool sampling is recommended, although no controlled studies have demonstrated the utility of three consecutive stool samples as is the case in *Giardia duodenalis* infection.

Preventing Exposure

HIV-infected persons should be educated and counseled concerning the different ways that *Cryptosporidium* can be transmitted **(BIII)**. Modes of transmission include having direct contact with infected adults, diaper-aged children, and infected animals; coming into contact with contaminated water during recreational activities; drinking contaminated water; and eating contaminated food.

Scrupulous handwashing can reduce the risk for diarrhea in HIV-infected persons, including diarrhea caused by *Cryptosporidium (242)*. HIV-infected persons should be advised to wash their hands after potential contact with human feces (including after diapering small children) and after the following activities: handling pets or other animals, gardening or other contact with soil, before preparing food, before eating, and before and after sex **(BIII)**. HIV-infected persons should avoid unprotected sex practices, especially practices that could lead to direct (e.g., oral-anal) or indirect (e.g., penile-anal) contact with feces. Patients should be advised to use barriers during sex to reduce such exposures (e.g., condoms, dental dams) **(BIII)**.

HIV-infected persons (particularly those with $CD4^+$ counts < 200 cells/μL), should avoid direct contact with diarrhea or stool from pets, particularly any stray pets, or dogs and cats aged <6 months **(BIII)**. Gloves should be worn when handling feces or cleaning areas that might have been contaminated by feces from pets **(BIII)**. HIV-infected persons should limit or avoid direct exposure to calves and lambs (e.g., farms, petting zoos) **(BII)**. Paying attention to hygiene and avoiding direct contact with stool are important when visiting premises where these animals are housed or exhibited.

HIV-infected persons should not drink water directly from lakes or rivers **(AIII)**. Waterborne infection also can result from swallowing water during recreational activities. HIV-infected persons should be aware that lakes, rivers, and salt water beaches and some swimming pools, recreational water parks, and ornamental water fountains might be contaminated with human or animal waste that contains *Cryptosporidium*. They should avoid swimming in water that is likely contaminated and should avoid swallowing water while swimming or playing in recreational water **(BIII)**.

Outbreaks of cryptosporidiosis have been linked to drinking water from municipal water supplies. During outbreaks or in other situations that impose a community advisory to boil water, boiling water for at least 3 minutes will eliminate the risk for cryptosporidiosis **(AIII)**. Using submicron personal-use water filters (home/office types) or bottled water might also reduce the risk for infection from municipal and well water **(CIII)**.

The magnitude of the risk for acquiring cryptosporidiosis from drinking water in a non-outbreak setting is uncertain, and available data are inadequate to recommend that all HIV-infected persons boil water or avoid drinking tap water in non-outbreak settings. However, HIV-infected persons who wish to take independent action to reduce the risk for waterborne cryptosporidiosis might take precautions similar to those recommended during outbreaks. Persons who opt to use a personal-use filter or bottled water should be aware of the complexities involved in selecting appropriate products, the lack of enforceable standards for the destruction or removal of oocysts, the costs of the products, and the logistic difficulty of using these products consistently.

Persons who take precautions to avoid acquiring cryptosporidiosis from drinking water should be advised that ice made from contaminated tap water also can be a source of infection. Such persons also should be aware that fountain beverages served in restaurants, bars, theaters, and other places also might pose a risk because these beverages, and the ice they contain, are usually made from tap water. Nationally distributed brands of bottled or canned carbonated soft drinks are safe to drink. Commercially packaged noncarbonated soft drinks and fruit juices that do not require refrigeration until after they are opened (i.e., can be stored unrefrigerated on grocery shelves) are also safe. Nationally distributed brands of frozen fruit juice concentrate are safe if the user reconstitutes them with water from a safe water source. Fruit juices that must be kept refrigerated from the time they are processed to the time of consumption might be either fresh (i.e., unpasteurized) or heat-treated (i.e., pasteurized); only those juices labeled as pasteurized should be considered free of risk from *Cryptosporidium*. Other pasteurized beverages and beers also are considered safe to drink.

HIV-infected persons should avoid eating raw oysters because cryptosporidial oocysts can survive in oysters for >2 months and have been found in oysters taken from certain commercial oyster beds **(BIII)**. In a hospital, standard precautions (i.e., use of gloves and handwashing after removal of gloves) should be sufficient to prevent transmission of cryptosporidiosis from an infected patient to a susceptible HIV-infected person **(BIII)**. However, because of the potential for fomite transmission, some specialists recommend that HIV-infected persons, specifically persons who are severely immunocompromised, should not share a room with a patient with cryptosporidiosis **(CIII)**.

If HIV-infected persons travel in developing countries, they should be warned to avoid drinking tap water or using tap water to brush their teeth **(BIII)**. Ice that is not made from bottled water also should be avoided. Raw fruits or vegetables that might have been washed in tap water also should be avoided

(BIII). HIV-infected persons also should avoid other sources of *Cryptosporidium* oocytes as much as possible **(BIII)**. These include working directly with people with diarrhea; with farm animals, cattle, and sheep; and with domestic pets that are very young or have diarrhea. If exposure is unavoidable, then the use of gloves and good hand hygiene is recommended.

Preventing Disease

Because chronic cryptosporidiosis occurs primarily in persons with advanced immunodeficiency, appropriate initiation of ART before the patient becomes severely immunosuppressed should prevent this disease **(AIII)**. Rifabutin (RIF) or clarithromycin, when taken for MAC prophylaxis, have been found to protect against cryptosporidiosis (*243,244*). However, data are insufficient to warrant a recommendation for using rifabutin or clarithromycin as chemoprophylaxis for cryptosporidiosis.

Treatment of Disease

In the setting of severe immunosuppression, ART with immune restoration to a $CD4^+$ count >100 cells/μL leads to resolution of clinical cryptosporidiosis (*50,245*) and is the mainstay of treatment. Therefore, patients with cryptosporidiosis should be offered ART as part of the initial management of their infection **(AII)**. Management should include symptomatic treatment of diarrhea **(AIII)**. Rehydration and repletion of electrolyte losses by either the oral or IV route are important. Severe diarrhea can exceed >10 L/day among patients with AIDS, often requiring intensive support. Oral rehydration should be pursued aggressively with oral rehydration solutions **(AIII)**.

Multiple agents have been investigated in small randomized controlled clinical trials of HIV-infected adults, including nitazoxanide, paromomycin, spiramycin, bovine hyperimmune colostrum, and bovine dialyzable leukocyte extract. No pharmacologic or immunologic therapy directed specifically against *C. parvum* has been shown to be consistently effective when used without ART (*246,247*).

Nitazoxanide is an orally administered nitrothiazole benzamide with in vivo activity against a broad range of helminths, bacteria, and protozoa (*248–250*). It has been approved by the Food and Drug Administration (FDA) for treatment of *C. parvum* in children and adults. When administered for 3 days at 500 mg twice daily to HIV-uninfected adults with cryptosporidiosis, nitazoxanide resulted in higher rates of diarrhea resolution and oocyst-free stools than placebo (*248*). HIV-infected adults with cryptosporidiosis with $CD4^+$ >50 cells/μL treated with 500–1,000 mg twice daily of nitazoxanide for 14 days experienced substantially higher rates of parasitological cure and resolution of diarrhea than persons receiving placebo treatment (*249*). Data from a compassionate use program before the advent of combination ART, which included primarily white male adults with a median $CD4^+$ count ≤50 cells/μL, reported that a majority of patients experienced some degree of clinical response (reduction in frequency of total stool and of liquid stools), usually within the first week of treatment (*251*). Adverse events associated with nitazoxanide are limited and typically mild, and no important drug-drug interactions have been reported. Because of the clinical significance of cryptosporidiosis, a trial of nitazoxanide in conjunction with ART, but never instead of ART, may be considered **(CIII)**.

Paromomycin is a nonabsorbable aminoglycoside indicated for the treatment of intestinal amebiasis but not specifically approved for cryptosporidiosis. It is effective in high doses for the treatment of cryptosporidiosis in animal models (*252*). A meta-analysis of 11 published studies of paromomycin in humans reported a response rate of 67%; however, relapses were common, with long-term success rates of only 33%. A Cochrane review and a meta-analysis of the two randomized controlled trials comparing paromomycin with placebo among patients with AIDS found the drug was no more effective than placebo at reducing diarrheal frequency or parasite burden (*246,247,253,254*). In persons with $CD4^+$ counts <100 cells/μL, a substantial clinical response to paromomycin is rare. Therefore, data do not support a recommendation for the use of paromomycin for cryptosporidiosis **(DII)**.

Treatment with antimotility agents (e.g., loperamide, tincture of opium) can palliate symptoms by reducing diarrheal frequency and volume, but these agents are not consistently effective **(BIII)**. Octreotide, a synthetic octapeptide analog of naturally occurring somatostatin that is approved for the treatment of secreting tumor-induced diarrhea, is no more effective than other oral antidiarrheal agents and is usually not recommended **(DII)** (*250*).

Monitoring and Adverse Events, Including Immune Reconstitution Inflammatory Syndrome (IRIS)

Patients should be monitored closely for signs and symptoms of volume depletion, electrolyte and weight loss, and malnutrition. Total parenteral nutrition might be indicated in certain patients **(CIII)**.

IRIS has not been described in association with treatment of cryptosporidiosis.

Management of Treatment Failure

Supportive treatment and optimizing ART to achieve full virologic suppression are the only feasible approaches to the management of treatment failure **(AIII)**.

Preventing Recurrence

No pharmacologic interventions are known to be effective in preventing the recurrence of cryptosporidiosis.

Special Considerations During Pregnancy

As with nonpregnant women, initial treatment should rely on rehydration and initiation of ART **(AII)**. Pregnancy should not preclude the use of ART. Nitazoxanide is not teratogenic in animals but human data on use in pregnancy are not available. Nitazoxanide may be used in pregnancy after the first trimester in severely symptomatic pregnant women **(CIII)**.

Microsporidiosis

Epidemiology

Microsporidia are protists related to fungi, defined by the presence of a unique invasive organelle consisting of a single polar tube that coils around the interior of the spore (*255,256*). They are ubiquitous organisms and are likely zoonotic and/or waterborne in origin (*257,258*). The microsporidia reported as pathogens in humans include *Encephalitozoon cuniculi*, *Encephalitozoon hellem*, *Encephalitozoon* (*syn Septata*) *intestinalis*, *Enterocytozoon bieneusi*, *Trachipleistophora hominis*, *Trachipleistophora anthropophthera*, *Pleistophora species*, *P. ronneafiei*, *Vittaforma* (*syn Nosema*) *corneae*, *Microsporidium sp.*, *Nosema ocularum*, *Anncaliia* (*syns Brachiola/Nosema*) *connori*, *Anncaliia* (*syn Brachiola*) *vesicularum*, and *Anncaliia* (*syns Brachiola/Nosema*) *algerae (255–257,259–262*). In the pre-ART era, reported prevalence rates of microsporidiosis varied between 2% and 70% among HIV-infected patients with diarrhea, depending on the diagnostic techniques employed and the patient population described (*255–257,259*). The incidence of microsporidiosis has declined with the widespread use of effective ART, but is still being detected in HIV-infected persons unable to access or continue with ART. Among non-HIV-infected persons, microsporidiosis is being increasingly recognized in children, travelers, organ transplant recipients, and the elderly. In the immunosuppressed host, clinical signs related to microsporidiosis are most commonly observed when the $CD4^+$ count is <100 cells/μL (*255-257,259*).

Clinical Manifestations

The most common manifestation of microsporidiosis is gastrointestinal tract infection with diarrhea; however, encephalitis, ocular infection, sinusitis, myositis, and disseminated infection also are described (*255–257,259*).

Clinical syndromes can vary by infecting species. *E. bieneusi* is associated with malabsorption, diarrhea, and cholangitis. *E. cuniculi* is associated with hepatitis, encephalitis, and disseminated disease. *E. intestinalis* is associated with diarrhea, disseminated infection, and superficial keratoconjunctivitis. *E. hellem* is associated with superficial keratoconjunctivitis, sinusitis, respiratory disease, prostatic abscesses, and disseminated infection. *Nosema*, *Vittaforma*, and *Microsporidium* are associated with stromal keratitis following trauma in immunocompetent hosts. *Pleistophora*, *Anncaliia*, and *Trachipleistophora* are associated with myositis. *Trachipleistophora* is associated with encephalitis and disseminated disease.

Diagnosis

Although microsporidia belonging to the genera *Encephalitozoon*, *Anncaliia*, *Vittaforma*, and *Trachipleistophora* have been cultivated in vitro, *E. bieneusi* has not been successfully cultivated in vitro. Effective morphologic demonstration of microsporidia by light microscopy can be accomplished by staining methods that produce differential contrast between the spores of the microsporidia and the cells and debris in clinical samples (e.g., stool). In addition, because of the small size of the spores (1–5 mm), adequate magnification (e.g., 1,000X) is required for visualization. Chromotrope 2R, calcofluor white (a fluorescent brightener), and Uvitex 2B (a fluorescent brightener) are useful as selective stains for microsporidia in stool and other body fluids (*262*).

In biopsy specimens, microsporidia can be visualized with Giemsa, tissue Gram stains (Brown-Hopps Gram stain), calcofluor white or Uvitex 2B (fluorescent brighteners) staining, Warthin-Starry silver staining, hematoxylin and eosin, or Chromotrope 2A (*262*). In gastrointestinal disease**,** examination of three stools with chromotrope and chemofluorescent stains is often sufficient for diagnosis. If stool examination is negative and microsporidiosis is suspected, a small bowel biopsy should be performed. If the etiologic agent is *Encephalitozoon* or *Trachipleistophora spp.*, examination of urine often also reveals the organism. Determination of the species of microsporidia causing disease can be made by the morphology of the organism demonstrated by transmission electron microscopy, by staining with species-specific antibodies, or by PCR using species- or genus-specific primers (*262*). Assistance of specialists familiar with the species differentiation of microsporidia should be sought.

Preventing Exposure

Patients with AIDS (e.g., $CD4^+$ count <200 cells/μL) should avoid untreated water sources **(AIII).** Otherwise, other than general attention to handwashing and other personal hygiene measures, no precautions to reduce exposure to microsporidia are recommended.

Preventing Disease

No chemoprophylactic regimens are known to be effective in preventing microsporidiosis.

Treatment of Disease

ART with immune restoration (an increase of $CD4^+$ count to >100 cells/μL) is associated with resolution of symptoms of enteric microsporidiosis, including that caused by *E. bieneusi (245,263-265*). All patients should be offered ART as part of the initial management of microsporidial infection **(AII)**. Data suggest that following successful ART, immune reconstitution occurs and enables the patient's own defenses to eradicate microsporidia (*245,264*).

No specific therapeutic agent is available for *E. bieneusi* infection. A controlled clinical trial suggested that *E. bieneusi* might respond to oral fumagillin (60 mg/day), a water-insoluble antibiotic made by *Aspergillus fumigatus* **(BII)** (*266,267*), or to its synthetic analog TNP-470 **(BIII)** (*268*). However, fumagillin and TNP-470 are not available for systemic use in the United States. One report indicated that treatment with nitazoxanide for 60 days might resolve chronic diarrhea caused by *E. bieneusi* in the absence of ART (*269*); however, the effect appeared to be minimal among patients with low $CD4^+$ counts. Therefore, this drug cannot be recommended with confidence **(CIII).**

Albendazole, a benzimidazole that binds to β-tubulin, has activity against many species of microsporidia, but it is not effective against *Enterocytozoon* infections or *V. corneae.* The tubulin genes of both *E. bieneusi (270*) and *V. corneae (271*) have amino acid residues associated with albendazole resistance. Therefore, albendazole is recommended for initial therapy of intestinal and disseminated microsporidiosis caused by microsporidia other than *E. bieneusi* and *V. corneae* **(AII)** (*272–274*).

Itraconazole might be useful in disseminated disease when combined with albendazole, especially in infections caused by *Trachipleistophora* or *Anncaliia* **(CIII).**

Ocular infections caused by microsporidia should be treated with topical Fumidil B (fumagillin bicylohexylammonium) in saline (to achieve a concentration of 70 μg/mL of fumagillin) **(BII)** (*273*). Topical fumagillin is the only formulation available for treatment in the United States and is investigational. Although clearance of microsporidia from the eye can be demonstrated, the organism often is still present systemically and can be detected in urine or in nasal smears. Therefore, the use of albendazole as a companion systemic agent to fumagillin is recommended in ocular infections **(BIII).**

Metronidazole and atovaquone are not active in vitro or in animal models and should not be used to treat microsporidiosis **(DII)**. Fluid support should be offered if diarrhea has resulted in dehydration **(AIII)**. Patients with malnutrition and wasting should be treated with nutritional supplementation **(AIII)**. Antimotility agents can be used if required for diarrhea control **(BIII).**

Monitoring and Adverse Events, Including Immune Reconstitution Inflammatory Syndrome (IRIS)

Albendazole side effects are rare but hypersensitivity (rash, pruritis, fever), neutropenia (reversible), CNS effects (dizziness, headache), gastrointestinal disturbances (abdominal pain, diarrhea, nausea, vomiting), hair loss (reversible), and elevated hepatic enzymes (reversible) have been reported. Albendazole is not known to be carcinogenic or mutagenic. Topical fumagillin has not been associated with substantial side effects. Oral fumagillin has been associated with thrombocytopenia, which is reversible on stopping the drug.

An IRIS has not been described in association with treatment for *E. bieneusi* or non-*E. bieneusi* microsporidiosis.

Management of Treatment Failure

Supportive treatment and optimizing ART to attempt to achieve full virologic suppression are the only feasible approaches to the management of treatment failure **(AIII).**

Preventing Recurrence

Treatment for ocular microsporidiosis should be continued indefinitely because recurrence or relapse might follow discontinuation of treatment **(BIII).** Whether treatment of other manifestations can be safely discontinued after immune restoration with ART is unknown; however, such a practice is reasonable, based on experience with discontinuation of secondary prophylaxis (chronic maintenance therapy) for other OIs present during advanced HIV disease. Therefore, certain specialists recommend discontinuing chronic maintenance therapy if patients no longer have signs and symptoms of microsporidiosis and have a sustained (e.g., >6 months) increase in their $CD4^+$ counts to levels >200 cells/μL after ART **(BIII)** (*245*).

Special Considerations During Pregnancy

The primary approach to treatment of microsporidiosis in pregnancy should be initiation of ART to restore immune function. Among animals (i.e., rats and rabbits), albendazole is embryotoxic and teratogenic at dosages of 20 mg/kg body weight. Therefore, albendazole is not recommended for use among pregnant women **(DIII).** However, well-controlled studies in human pregnancy have not been performed. Systemic fumagillin has been associated with increased resorption and growth retardation in rats. No data on use in human pregnancy are available. However, because of the

antiangiogenic effect of fumagillin, this drug should not be used among pregnant women **(EIII).** Topical fumagillin has not been associated with embryotoxic or teratogenic effects among pregnant women and may be considered when therapy with this agent is appropriate **(CIII).**

Mycobacterium tuberculosis Infection and Disease

Epidemiology

The World Health Organization (WHO) estimates that TB is the cause of death for 13% of persons with AIDS (*275*). TB infection occurs when a susceptible person inhales droplet nuclei containing *Mycobacterium tuberculosis* organisms, generated when persons with pulmonary or laryngeal TB disease cough, sneeze, shout, or sing (*276*). Usually within 2–12 weeks after infection, the immune response limits multiplication of tubercle bacilli. However, viable bacilli persist for years, a condition referred to as latent TB infection (LTBI). Persons with LTBI are asymptomatic and are not infectious. TB disease can develop immediately after exposure (primary disease) or after reactivation of LTBI (reactivation disease). Primary disease accounts for one third or more of cases of TB disease in HIV-infected populations (*277*).

Overall case rates of TB in the United States are declining, with 4.4 new cases of TB disease per 100,000 population (a total of 13,299 cases) reported in 2007 *(278*) and an estimated 4.0% prevalence of LTBI in the general population (*279*). Similarly, health-care–associated outbreaks of TB are now uncommon in the United States, partly because of improved public health and hospital TB-control programs (*280*). The percentage of patients with TB and with known HIV infection also decreased from 15.0% in 2003 to 12.4% in 2006, although the percentage of TB cases with unknown HIV status increased from 28.7% in 2005 to 31.7% in 2006 *(281*), which might reflect either a lack of HIV testing or incomplete reporting of HIV test results (*278*).

The estimated annual risk for active TB among persons with LTBI in the general population is 12.9 per 1,000 person-years of observation. In contrast, rates of progression to active TB among HIV-infected persons with LTBI have ranged from 35 to 162 per 1,000 person-years of observation (*282–284*). Unlike other AIDS-related OIs, $CD4^+$ count is not a reliable predictor of increased risk for TB disease in HIV-infected persons. In both TB-endemic and non-TB-endemic areas, patients can have relatively high $CD4^+$ counts at the time HIV-related TB disease develops. As with HIV-uninfected persons, HIV-infected persons who live or work in high-risk congregate settings such as correctional facilities, health-care facilities, drug-treatment units, or homeless shelters are at increased risk for acquiring TB.

Clinical Manifestations

Persons with LTBI are, by definition, asymptomatic. Among HIV-infected persons, the presentation of active TB disease is influenced by the degree of immunodeficiency (*285,286*). In addition, early after initiating ART in severely immunosuppressed patients, previously unrecognized subclinical TB can be unmasked by reconstitution of the immune system (*287,288*).

In HIV-infected patients without pronounced immunodeficiency (e.g., $CD4^+$ count >350 cells/μL), HIV-related TB clinically resembles TB among HIV-uninfected persons. The majority of patients have disease limited to the lungs, and common chest radiographic manifestations include upper lobe fibronodular infiltrates with or without cavitation (*289*). However, extrapulmonary disease is more common in HIV-infected persons than in HIV-uninfected persons, regardless of $CD4^+$ counts, although clinical manifestations are not substantially different from those described in HIV-uninfected persons. TB must be ruled out in diseases of every organ (*290*) but especially those related to CNS or meningeal symptoms in which early TB treatment is essential to improve outcomes (*291,292*).

In advanced HIV disease, the chest radiographic findings of pulmonary TB are markedly different compared with those among patients with less severe immunosuppression. Lower lobe, middle lobe, interstitial, and miliary infiltrates are common and cavitation is less common (*285,289,293*). Marked mediastinal lymphadenopathy also can be found. Even with normal chest radiographs, patients with HIV infection and pulmonary TB might have acid fast bacilli (AFB)-positive sputum smear and culture results.

With increasing degrees of immunodeficiency, extrapulmonary TB (e.g., lymphadenitis, pleuritis, pericarditis, and meningitis), with or without pulmonary involvement, is more common, and found in the majority of TB patients with $CD4^+$ counts <200 cells/μL. Among such patients, TB can be a severe systemic disease with high fevers, rapid progression, and sepsis syndrome.

Histopathologic findings also are affected by the degree of immunodeficiency. Patients with relatively intact immune function have typical granulomatous inflammation associated with TB disease. With progressive immunodeficiency, granulomas become poorly formed or can be completely absent (*286*).

In severely immunodeficient patients with a high mycobacterial load, TB disease may be subclinical or oligo-symptomatic. After initiation of ART, immune reconstitution might unmask

active TB, resulting in pronounced inflammatory reactions at the sites of infection (*294–298*). This type of IRIS can manifest as early as 7 days after starting ART. Signs and symptoms include fever; weight loss; and signs of local inflammatory reactions such as lymphadenitis, pulmonary consolidation, infiltrates, nodules, and effusions. Histologically, a vigorous granulomatous reaction, with or without caseation, but with suppuration, necrotising inflammation, and AFB might be evident; cultures of this material are almost invariably positive for *M. tuberculosis*.

Diagnosis

Diagnosis of Latent Tuberculosis Infection (LTBI)

All persons should be tested for LTBI at the time of HIV diagnosis regardless of their TB risk category **(AII)**. Persons with negative diagnostic tests for LTBI, advanced HIV infection ($CD4^+$ count <200 cells/μL), and without indications for initiating empiric LTBI treatment should be re-tested for LTBI once they start ART and attain a $CD4^+$ count ≥200 cells/μL **(AIII)**. In general, annual testing for LTBI is recommended for HIV-infected persons who are or remain in a "high-risk" category for repeated or ongoing exposure to persons with active TB, i.e., persons who are or who have been incarcerated, live in congregate settings, are active drug users, or have other sociodemographic risk factors for TB **(AIII)**. All HIV-infected persons with a positive diagnostic test for LTBI should undergo chest radiography and clinical evaluation to rule out active TB **(AI)**.

Diagnosis of LTBI can be accomplished with one of two approaches. The tuberculin skin test (TST), placed by the Mantoux method, is considered positive in HIV-infected persons if induration of ≥5 mm is demonstrated 48–72 hours after the intradermal placement of 0.1 mL purified protein derivative (PPD). Recently, new in vitro assays that detect IFN-γ release in response to *M. tuberculosis*-specific peptides have been developed for diagnosing LTBI (*299*). Given the high risk for progression to active disease in HIV-infected persons, any HIV-infected person with reactivity on any of the current LTBI diagnostic tests should be considered infected with *M. tuberculosis* (Figure 1) (*300*).

Evidence suggests that the IGRAs have more consistent and higher specificity (92%–97%) compared with TST (56%–95%), better correlation with surrogate measures of exposure to *M. tuberculosis*, and less cross reactivity because of Bacillus Calmette-Guérin (BCG) vaccination or other nontuberculous mycobacteria exposure than the TST (*299,301*). Three IGRAs are FDA-approved and available in the United States: the QuantiFERON®-TB Gold and the QuantiFERON®-TB Gold In-Tube (Cellestis Limited), and the T-SPOT™.*TB* test (Oxford Immunotec) is awaiting final FDA approval (Table 10). For both the TST and IGRAs, however, HIV-related immunosuppression might be associated with false-negative results (*302*). The frequency of false-negative and indeterminate IGRA results increases with advancing immunodeficiency (*303,304*).

Results from comparative studies of TST and IGRAs in HIV-infected patients indicate that concordance between the tests is not complete *(305,306*). The TST remains useful for diagnosing LTBI, particularly for patients who have not been vaccinated for BCG and in settings with cost constraints. The optimal application of IGRAs in HIV-infected persons will be better defined when the results of ongoing studies become available *(301*). IGRAs might be used in combination with TST to improve sensitivity and specificity for detection of LTBI (*301*).

Fibrotic lesions consistent with TB might be incidentally noted on a chest radiograph obtained for other reasons. Persons with fibrotic lesions should undergo diagnostic testing for LTBI and be evaluated for active disease. Unless the patient has a known history of prior adequate treatment for active TB, sputum samples for AFB smear and culture should be obtained even if the patient is asymptomatic. HIV-infected persons with $CD4^+$ counts <200 cells/μL who have fibrotic lesions consistent with TB on a chest radiograph and no prior history of treatment should be considered as having *M. tuberculosis* infection irrespective of the results of LTBI diagnostic tests. In situations with moderate-to-high suspicion of active TB regardless of the results of LTBI tests, empiric treatment for active TB should be initiated while awaiting the results of further diagnostic tests **(AII).**

Diagnosis of Active Tuberculosis

The evaluation of suspected HIV-related TB should include a chest radiograph regardless of the possible anatomic site of disease. Sputum samples for AFB smear and culture should be obtained from patients with pulmonary symptoms and chest radiographic abnormalities. A normal chest radiograph does not exclude the possibility of active pulmonary TB and when suspicion for disease is high, sputum samples should still be obtained (*289,307*). Obtaining three unique specimens, preferably in the morning of different days, increases the yield for both smear and culture (*308*). TST and IGRAs should not be relied upon for the diagnosis of TB disease. Approximately one fourth of HIV-infected persons with pulmonary TB disease have false-negative results (*301*).

HIV serostatus does not affect the yield from sputum smear and culture examinations; positive smear results are more common in cavitary pulmonary disease (*309*). The yield of AFB smear and culture of specimens from extrapulmonary sites is greater among patients with advanced immunodeficiency

compared with HIV-uninfected adults (*310-312*). Nucleic acid amplification (NAA) tests, also called "direct amplification tests," can be applied directly to clinical specimens such as sputum and help to evaluate persons with a positive AFB smear. A positive NAA result in an AFB smear-positive patient likely reflects active TB. In persons with AFB smear-negative sputum or extrapulmonary disease, however, NAA tests have lower sensitivity and negative predictive value and should be used and interpreted with caution (*299*).

For patients with signs of extrapulmonary TB, needle aspiration or tissue biopsy of skin lesions, lymph nodes, or pleural or pericardial fluid should be performed. Mycobacterial blood cultures might be helpful for patients with signs of disseminated disease or worsening immunodeficiency.

A positive AFB smear result in any specimen (sputum, needle aspirate, tissue biopsy) represents some form of mycobacterial disease but does not always represent TB. Because TB is the most virulent mycobacterial pathogen and can be spread from person to person, patients with smear-positive results should be considered to have TB disease until definitive mycobacterial species identification is made. Automated liquid media culture systems might indicate growth of *M. tuberculosis* within 1–3 weeks compared with 3–8 weeks in solid media.

Drug-susceptibility testing and adjustment of the treatment regimen based on results are critical to the successful treatment of patients with TB and to curbing transmission of drug-resistant *M. tuberculosis*. For all patients with TB disease, testing for susceptibility to first-line agents (isoniazid [INH], rifampin [RIF], ethambutol [EMB], and pyrazinamide [PZA]) should be performed, regardless of the source of the specimen. Drug susceptibility tests should be repeated if sputum cultures remain positive for *M. tuberculosis* after 3 months of treatment or become positive after 1 month or longer of negative cultures (*308*). Second-line drug susceptibility testing should be performed only in reference laboratories and should be limited to specimens from patients who 1) have had previous therapy, 2) are contacts of patients with drug-resistant TB disease, 3) have demonstrated resistance to RIF or to other first-line drugs, 4) have positive cultures after 3 months of treatment, or, 5) are from regions with a high prevalence of multiple drug-resistant (MDR) or extensively drug-resistant (XDR) TB (*313*).

Molecular beacons, phage-based assays, and line probe assays are three methods for rapidly detecting the presence of drug resistance, specifically to INH and RIF. These assays are expensive, require sophisticated laboratory support, need further study, and are not yet FDA-approved for use in the United States. Published results on the performance of the two assays suitable for direct use on samples, the INNO-LiPA Rif. TB kit (Innogenetics, Gent, Belgium) and FASTPlaque-TB (Biotec Laboratories Ltd., Ipswich, United Kingdom), have been inconsistent. Until results of ongoing validation and field testing of these rapid tests are available, conventional laboratory methods for culture and susceptibility testing should be pursued on all suspect clinical specimens.

Preventing Exposure

HIV-infected persons should be advised that time spent in congregate settings or other environments identified as possible sites of TB transmission (e.g., correctional facilities, homeless shelters, nursing homes) might increase the likelihood of contracting *M. tuberculosis* infection **(BIII)** (*277*)**.** Factors known to increase contagiousness include anatomical site of TB disease (pulmonary or laryngeal), AFB smear-positive sputum, cavities evident on chest radiograph, and aerosolization by coughing or singing. HIV-infected patients who have pulmonary or laryngeal TB are, on average, as contagious as patients who are not HIV-infected. Exposure to patients with known TB, but who have AFB smear-negative sputum results, poses a lower but not nonexistent risk for *M. tuberculosis* transmission (*276,314*).

In health-care facilities and other environments with a high risk for transmission, all patients with known or presumed infectious TB should be physically separated from other patients, but especially from those with HIV infection **(AII)** (*276*). A patient with infectious TB returning to a congregate living setting or to any setting in which susceptible persons might be exposed should be receiving or should have completed treatment and have three consecutive negative AFB smear results from good quality sputum samples collected ≥8 hours apart (with one specimen collected during the early morning), be on adequate treatment for >2 weeks, and demonstrate clinical improvement before being considered noninfectious **(AIII)** (*276,280,315*). Certain specialists recommend that patients with MDR-TB have a negative sputum culture before returning to a congregate setting.

Treatment of LTBI is effective in reducing TB incidence among populations who reside in areas of low, medium, and high TB transmission (*316–318*). All possible strategies should be pursued to ensure that HIV-infected persons with risk factors for TB are tested for *M. tuberculosis* infection and those with LTBI receive and complete a course of LTBI treatment **(AII)** (*319*). Persons infected with HIV should be treated presumptively for LTBI when the history of TB exposure is substantial, regardless of the results of diagnostic testing for LTBI **(BII)** (*276,282,283*)**.** Use of BCG vaccine is not recommended as a means to control TB in the United States because of the unproven efficacy of the vaccine in the U.S. population and the success of other measures in reducing TB incidence (*319*). BCG vaccination for HIV-infected persons is

contraindicated because of its potential to cause disseminated disease **(EII).**

Preventing Disease (Treatment of LTBI)

All HIV-infected persons with suspected LTBI or who have symptoms indicating TB should promptly undergo chest radiography and clinical evaluation to rule out active TB regardless of the results of diagnostic tests for LTBI (*320*).

HIV-infected persons, regardless of age, should be treated for LTBI if they have no evidence of active TB and exhibit the following characteristics: 1) a positive diagnostic test for LTBI and no prior history of treatment for active or latent TB **(AI)**; 2) a negative diagnostic test for LTBI but are close contacts of persons with infectious pulmonary TB **(AII)**; and 3) a history of untreated or inadequately treated healed TB (i.e., old fibrotic lesions on chest radiography) regardless of diagnostic tests for LTBI **(AII)** (*321*).

The efficacy of LTBI treatment has not been documented for HIV-infected persons with negative diagnostic tests for LTBI without known exposure to *M. tuberculosis.* Persons from groups or geographic areas with a high prevalence of *M. tuberculosis* infection might be at increased risk for primary or reactivation TB and, in this situation, decisions to treat for LTBI must include consideration of $CD4^+$ count and other factors **(BIII)** (*282,283,320*)**.**

Treatment options for LTBI include INH daily **(AII)** or twice weekly **(BII)** for 9 months (*282,283,322*). Results from a randomized clinical trial comparing INH daily therapy for 9 months with 12 doses of once-weekly INH-rifapentine are pending (*323*). Because of an increased risk for fatal and severe hepatotoxicity, a 2-month regimen of daily RIF and PZA is not recommended for LTBI treatment regardless of HIV status **(DI)** (*277*). HIV-infected persons receiving INH should receive pyridoxine **(BIII)** to minimize the risk for developing peripheral neuropathy. Alternatives for persons who cannot take INH or who have been exposed to a known INH-resistant index patient include either RIF or rifabutin alone for 4 months **(BIII).** Decisions to use a regimen containing either RIF or rifabutin should be made after considering potential drug interactions (see the section on ART in the Management of TB Disease). For persons exposed to INH- and/or RIF-resistant TB, decisions to treat with one or two drugs other than INH, RIF, or rifabutin should be based on the relative risk for exposure to organisms broadly resistant to other antimycobacterial drugs and should be made in consultation with public health authorities **(AII).** Directly observed therapy (DOT) should be used with intermittent dosing regimens **(AI)** when otherwise feasible to maximize regimen-completion rates (*282,283*)**.**

No evidence suggests that LTBI treatment should be continued beyond the recommended duration in persons with HIV infection. Therefore, LTBI treatment should be discontinued after completing the appropriate number of doses **(AII).**

Treatment of Disease

Considering the variability of yield from smear microscopy and NAA tests, empiric treatment should be initiated and continued in HIV-infected persons in whom TB is suspected until all diagnostic work-up (smears, cultures, or other identification results) is complete **(AII)**. When active TB is diagnosed or suspected, a multi-drug anti-TB treatment regimen should be started immediately **(AI)**. This approach promotes rapid killing of tubercle bacilli, prevents the emergence of drug resistance, and decreases the period of contagion (*48*). DOT is recommended for all patients with HIV-related TB **(AII)**. Likelihood of treatment success is further enhanced by DOT with support for other social and medical needs of HIV-infected patients **(BII)** (enhanced DOT) (*48*). A treatment plan should be based on completion of the total number of recommended doses ingested rather than the duration of treatment administration **(AIII)** (*277*). The following text summarizes both duration-based and total number-based dosing recommendations.

Recommendations for anti-TB treatment regimens in HIV-infected adults follow the same principles as for adults without HIV infection **(AI)** (*48*). Treatment of drug-susceptible TB disease should include a 6-month regimen with an initial phase of INH, RIF or rifabutin, PZA, and EMB administered for 2 months, followed by INH and RIF (or rifabutin) for 4 additional months **(AI)**. When drug-susceptibility testing confirms the absence of resistance to INH, RIF, and PZA, EMB may be discontinued before 2 months of treatment have been completed **(AI)** (*277*). For patients with cavitary lung disease and cultures positive for *M. tuberculosis* after completion of 2 months of therapy, treatment should be extended with INH and RIF for an additional 3 months for a total of 9 months **(AII)**. All HIV-infected patients treated with INH should receive pyridoxine supplementation **(BIII)**. For patients with extrapulmonary TB, a 6- to 9-month regimen (2 months of INH, RIF, PZA, and EMB followed by 4–7 months of INH and RIF) is recommended **(AII)**. Exceptions to the recommendation for a 6- to 9-month regimen for extrapulmonary TB include CNS disease (tuberculoma or meningitis) and bone and joint TB, for which many experts recommend 9–12 months **(AII)** (*277*). Adjuvant corticosteroids should be added when treating CNS and pericardial disease **(AII)**. Treatment with corticosteroids should be started intravenously as early as possible with change to oral therapy individualized according to clinical improvement (Table 3). Recommended corticosteroid regimens are dexamethasone 0.3–0.4 mg/kg tapered over 6–8 weeks (*324*) or prednisone 1 mg/kg for 3 weeks, then tapered for 3–5 weeks**.**

The optimal way to prevent relapse has not been determined. How the CD4+ count relates to likelihood of treatment failure and relapse remains uncertain. Some recent observational studies suggest that 9 months of therapy result in a lower rate of relapse than shorter or 6-month anti-TB regimens (*325–327*). While awaiting definitive results of randomized comparisons of treatment duration in HIV-infected patients with TB disease, 6 months of therapy are probably adequate for the majority of patients, but prolonged therapy (up to 9 months) is recommended (as in HIV-uninfected patients) for patients with a delayed response to therapy, with cavitary disease on chest radiograph, and for those with extrapulmonary or CNS disease **(BII)** (*48*)**.**

Intermittent dosing (i.e., twice or thrice weekly) facilitates DOT by decreasing the number of encounters required, might provide more effective peak serum concentrations, and is preferable to complete the regimen. For HIV-infected patients, the initial 8-week phase of therapy should be administered daily by DOT (7 days per week for 56 doses or 5 days per week for 40 doses) **(AII)** or 3 times weekly by DOT for 24 doses **(BII)** (*277*). Because twice-weekly administration of the continuation phase of therapy is associated with an increased risk for relapse with acquired rifamycin-resistant M. tuberculosis strains (*277*,*328–330*), for patients with CD4+ counts <100 cells/μL the continuation phase of either 4 months or 7 months should be administered either daily or three times weekly by DOT **(AIII)**. Twice-weekly continuation-phase therapy may be considered in patients with CD4+ counts ≥100 cells/μL **(CIII)**. Once-weekly administration of INH-rifapentine in the continuation phase should not be used for any patient with HIV infection **(EI)**.

Monitoring and Adverse Events, Including Immune Reconstitution Inflammatory Syndrome (IRIS)

Monitoring of LTBI Treatment

All patients with a diagnosis of LTBI should be counseled about risk for TB, adherence to treatment regimens, benefits and risks of treatment, interactions with other drugs, and an optimal follow-up plan. HIV-infected patients receiving treatment for LTBI also should have baseline laboratory testing, including an evaluation of hepatic function (serum aspartate aminotransferase [AST], bilirubin, and alkaline phosphatase) for patients treated with INH and a complete blood count and platelet count for patients taking RIF or rifabutin (*282,283*).

Patients being treated for LTBI should be monitored at least monthly with a history and physical assessment designed to detect hepatitis and neuropathy. Patients should be advised to stop treatment and promptly seek medical evaluation if symptoms suggesting hepatitis occur, such as nausea, vomiting, jaundice, or dark urine. Clinicians in all settings should consider dispensing no more than a 1-month supply of medication (*331,332*). Routine laboratory monitoring is indicated in HIV-infected patients with abnormal baseline liver-function tests, with chronic liver disease, or in those receiving treatment with ART **(***282,283,333*).

Monitoring of Active TB Disease Treatment

A baseline evaluation and monthly follow-up consisting of clinical, bacteriologic, and periodic laboratory and radiographic evaluations are essential to ensure treatment success. Clinical history and baseline tests to evaluate hepatic function (AST, bilirubin, and alkaline phosphatase), renal function (serum creatinine), complete blood count (including platelet count), and CD4+ counts are recommended for all patients (*277*). HIV-infected patients being treated for active TB should have a clinic-based evaluation at least monthly. For patients with extrapulmonary TB, the frequency and types of evaluations will depend on the sites involved and the ease with which specimens can be obtained. For patients with pulmonary TB, at least one sputum specimen for AFB smear and mycobacterial culture should be obtained monthly until two consecutive specimens are culture negative. Sputum specimens should be obtained after 8 weeks of treatment to inform clinical decision-making about the duration of the continuation phase. For patients with positive AFB smears at initiation of treatment, follow-up smears may be obtained at more frequent intervals (e.g., every 2 weeks until two consecutive specimens are negative) to provide an early assessment of the treatment response (*277*).

For patients with positive *M. tuberculosis* cultures after 3 months of treatment, drug-susceptibility tests should be repeated on newly acquired sputum specimens. Patients with positive *M. tuberculosis* cultures after 4 months of treatment should be considered as treatment failures and managed accordingly (*44*). At each visit, patients should be questioned about adherence and possible adverse effects of anti-TB medications; those taking EMB should be asked about blurred vision or scotomata and tested for visual acuity and color discrimination. Routine laboratory monitoring during treatment, even when baseline laboratory abnormalities are not present, could be considered **(***333*).

In HIV-infected persons with active TB, serum concentrations of the first-line anti-TB drugs are frequently lower than published normal ranges (*334*). However, routine drug-level monitoring is not recommended (*277*). For those with a slow response to treatment, drug concentration measurements might provide objective information on which to base modifications of treatment (*335*).

Management of Common Adverse Events

Although the reported frequency of anti-TB drug-related toxicity in patients with HIV infection varies, for most adverse events, rates are not different than for HIV-uninfected patients (*333,336–339*). Because alternative drugs often have less efficacy and more toxicities than first-line anti-TB drugs and diagnosing a drug reaction and determining the responsible agent can be difficult, the first-line drugs (especially INH, RIF, or rifabutin) should not be stopped permanently without strong evidence that the specific anti-TB drug was the cause of the reaction. In such situations, consultation with a specialist in treating LTBI or TB in persons with HIV infection is recommended (*48*).

Gastrointestinal reactions are common with many of the anti-TB medications (*340*). If gastrointestinal symptoms occur, AST and bilirubin should be measured, and if the AST level is less than three times the upper limit of normal (ULN) or the baseline for the patient, the symptoms are assumed not to be caused by hepatic toxicity. Typically, gastrointestinal symptoms should be managed without discontinuing TB medications; initial approaches should include either changing the hour of administration or administering drugs with food.

Skin rashes are common with all of the anti-TB drugs. If rash is minor, affects a limited area, or causes pruritis, antihistamines should be administered for symptomatic relief and all anti-TB medications continued. If the rash is severe, all TB medications should be stopped until the rash is substantially improved, and TB drugs restarted one by one at intervals of 2–3 days. RIF or rifabutin should be restarted first (because they are least likely to cause rash and their role in treatment is critical). If the rash recurs, the last drug added should be stopped. If a petechial rash thought to be caused by thrombocytopenia occurs, the RIF or rifabutin should be stopped permanently (*341*). If a generalized rash associated with either fever or mucous membrane involvement occurs, all drugs should be stopped immediately, the patient should be switched to alternative anti-TB agents, and LTBI or TB treatment should be managed in consultation with a specialist.

Fever in an HIV-infected patient who has been receiving effective TB therapy for several weeks might represent drug fever, a paradoxical reaction, or IRIS (*342*). If superinfection or worsening TB is excluded as a potential cause, all TB drugs should be stopped**.** Once the fever has resolved, the general guidelines described for restarting/stopping drugs in the presence of a rash should be followed.

An increase in AST concentration occurs in approximately 20% of patients treated with the standard four-drug anti-TB regimen (*343*). Drug-induced liver injury can be caused by INH, rifamycins, or PZA and is defined as an AST elevation to ≥3 times the ULN in the presence of symptoms, or >5 times the ULN in the absence of symptoms (*344*). In addition to AST elevation, disproportionate increases in bilirubin and alkaline phosphatase occur occasionally. This latter pattern is more consistent with rifamycin hepatotoxicity than with INH or PZA hepatotoxicity. In most patients, asymptomatic aminotransferase elevations resolve spontaneously.

In the absence of symptoms, elevations of AST <3 times ULN should not prompt changes of TB therapy, but the frequency of clinical and laboratory monitoring should be increased. If AST levels are ≥5 times the ULN regardless of symptoms, >3 times the ULN with symptoms, or if a significant increase in bilirubin and/or alkaline phosphatase occurs, hepatotoxic drugs should be stopped, and the patient should be evaluated immediately. For any substantial new transaminase or bilirubin elevation, serologic testing for hepatitis A, B, and C should be performed and the patient questioned regarding symptoms suggestive of biliary tract disease and exposures to alcohol and other hepatotoxins.

If anti-TB drugs must be stopped for hepatotoxicity, substituting ≥3 nonhepatotoxic anti-TB drugs is prudent until the specific cause of hepatotoxicity can be determined and an alternative longer-term regimen constructed. The suspected anti-TB medications should be restarted one at a time after the AST level returns to <2 times the ULN or to near baseline for patients with pre-existing abnormalities. Because the rifamycins are a critical part of the TB regimen and are less likely to cause hepatotoxicity than INH or PZA (*343*), they should be restarted first. If no increase in AST occurs after 1 week, INH may be restarted. PZA may be restarted 1 week after INH if AST does not increase. If symptoms recur or AST increases, the last drug added should be stopped. If RIF and INH are tolerated and hepatitis was severe, PZA should be assumed responsible and should be discontinued. In this last circumstance, depending on the number of doses of PZA taken, severity of disease, and bacteriological status, therapy might be extended to 9 months with RIF and INH alone.

For HIV-infected patients on LTBI therapy who have hepatotoxicity, most of the general guidelines described for restarting/stopping drugs for patients on therapy for active TB apply. The ultimate decision regarding resumption of therapy with the same or a different agent for LTBI treatment should be made after weighing the risk for additional hepatic injury against the benefit of preventing progression to TB disease (*333*) and always in consultation with an expert in treating LTBI in persons with HIV infection.

ART in the Management of TB Disease

The treatment of TB can be complicated by drug interactions with the rifamycins and overlapping toxicities associated with

antiretrovirals (ARVs) and anti-TB drugs when therapy for both HIV and TB infections is concomitantly administered. Both RIF and rifabutin induce CYP3A enzymes, and although rifabutin is not as potent an inducer as RIF, it is a substrate, leading to drug interactions with the PIs and non-nucleoside reverse transcriptase inhibitors (NNRTIs) when these agents are concomitantly administered with the rifamycins; such administration might result in increased metabolism and suboptimal levels of ARVs (*345*).

Compared with PI-based regimens, NNRTI-based regimens have fewer interactions with RIF-based TB therapy (*346*). Rifabutin is an alternative to RIF and can be administered with PIs or NNRTIs with appropriate dose adjustments (*346*). Concomitant use of RIF with ritonavir-boosted PIs has been shown to result in subtherapeutic levels of the PI. Use of ritonavir-boosted saquinavir with RIF was associated with a high incidence of hepatotoxicity in a pharmacokinetic study using healthy volunteers (*347*). RIF should not be used in patients on PI-based regimens, with or without ritonavir-boosting **(EII)**. For patients undergoing treatment for active TB, starting ART with either an efavirenz- or nevirapine-based regimen is preferred because these NNRTIs have fewer interactions with RIF **(BII)**; dosage adjustments for these NNRTIs might be needed for persons weighing more than 60 kg **(BII)** (*348,349*). Delavirdine should not be used with either RIF or rifabutin (*350*).

If rifabutin is used in place of RIF, dosage reduction is required with boosted-PI regimens. Efavirenz decreases the levels of rifabutin, and the dose of the latter might have to be increased. Nevirapine does not affect the levels of rifabutin sufficiently to merit adjustment of the rifabutin dose. Underdosing of ARVs or rifabutin can result in selection of HIV drug-resistant mutants or acquired rifamycin resistance, respectively, whereas overdosing of rifabutin might result in dose-related toxicities such as neutropenia and uveitis. Because interpatient variations in the degree of enzyme induction or inhibition can occur, the use of therapeutic drug monitoring for levels of rifabutin, PIs, or NNRTIs might help to adjust dosing for individual patients.

HIV nucleos(tide) analogs and the fusion inhibitor enfuvirtide are not affected by the CYP enzymes and can be used with the rifamycins. Results of ongoing drug-drug interaction studies predict that the combination of RIF (and possibly rifabutin) will result in decreased levels of maraviroc, raltegravir, and elvitegravir. Until data are available to guide dose adjustment, these drugs in combination should be avoided or used with extreme caution. Available NNRTIs and PIs do not have clinically significant drug interactions with other first- and second-line anti-TB drugs; thus, when rifamycins cannot be administered because of toxicity or resistance (MDR or XDR *M. tuberculosis* strains), ART regimens should be selected on the basis of other factors appropriate to the patient **(AIII).**

Optimal Timing of Initiation of ART in ART-Naïve Patients with Active TB

For ART-naïve, HIV-infected persons who are diagnosed with active TB, anti-TB treatment must be started immediately **(AIII)**. The optimal timing of initiation of ART in this setting is not clear. Options include simultaneous TB and ART or treatment of TB first with delay of ART by several weeks to months. A positive aspect of starting both regimens simultaneously is the possible prevention of progressive HIV disease and reduction in morbidity or mortality associated with TB or other OIs. A negative of this approach is the possibility of overlapping toxicities, drug interactions, a high pill burden, and the possibility of developing IRIS or a paradoxical reaction. These factors must be weighed carefully when choosing the best time to start ART in individual patients.

Several randomized clinical trials are under way to address the optimal timing of initiation of ART in persons being treated for active TB, but the results will not be known for several years. Pending these results, certain specialists determine when to start ART based on the immunologic status of the patients (*339*,*351*,*352*). For patients with a $CD4^+$ count <100 cells/μL, ART should be started after ≥2 weeks of TB treatment **(BII)** to reduce confusion about overlapping toxicities, drug interactions (*339*), and the occurrence of paradoxical reactions or IRIS (*353*). For persons with a $CD4^+$ count of 100–200 cells/μL, certain specialists would delay ART until the end of the 2-month intensive phase of anti-TB treatment **(BII)**. In those with a sustained $CD4^+$ count >200 cells/μL, ART could be started during the anti-TB maintenance phase and for those with a $CD4^+$ count >350 cells/μL, after finishing anti-TB treatment **(BII)**. In one study, paradoxical reactions occurred in almost all HIV-infected patients with TB and a $CD4^+$ count <100 cells/μL who started ART within the first 30 days of TB therapy (*222*). However, other studies suggest this approach might prevent HIV disease progression or death (*222*,*339*,*353*). In a small, prospective, nonrandomized study of 49 HIV-infected patients from Brazil (*348*) treated with a RIF-based anti-TB regimen and efavirenz-based ART, morbidity and side effects of medications in patients who started ART 3 weeks after initiation of TB treatment were reduced, compared with those who started ART and anti-TB treatment simultaneously. Furthermore, simultaneous anti-TB and anti-HIV treatment did not reduce overall mortality.

When TB occurs in patients already on ART, treatment for TB must be started immediately **(AIII),** and ART should be modified to reduce the risk for drug interactions and maintain virologic suppression. When TB occurs in the setting of viro-

logic failure, ART drug-resistance testing should be performed and a new ART regimen constructed to achieve virologic suppression and avoid drug interactions with the anti-TB regimen administered **(AIII).**

Immune Reconstitution and Paradoxical Reactions

IRIS or a paradoxical reaction occurring after the initiation of ART is thought to be the result of recovery of immune responses to previously recognized TB antigens, reconstituted by ART or by TB treatment itself (*48*). The immune response might be an exaggerated inflammatory response during TB treatment in a patient known to have TB, referred to as paradoxical TB-associated IRIS, or might unmask previously undiagnosed TB, referred to as unmasking TB-associated IRIS.

TB-associated paradoxical reactions or IRIS usually occur in the first 1–3 months after starting ART in patients receiving TB treatment (*294*). The risk for IRIS is greater when ART is started within the first 2 months of TB therapy (*222,354*) and when the $CD4^+$ count is <100 cells/μL (*295-298*). Signs of a paradoxical reaction or IRIS can include, but are not limited to, high fevers, worsening respiratory status, increase in size and inflammation of involved lymph nodes or new lymphadenopathy, breakthrough meningitis or new or expanding CNS lesions, radiologic worsening of pulmonary parenchymal infiltrations, and increasing pleural effusions. Such findings should be attributed to a paradoxical or IRIS reaction only after a thorough evaluation has excluded other possible causes, especially failure of TB therapy.

IRIS or paradoxical reactions are usually self-limited but if symptoms are severe, supportive treatment might be required, depending on the nature of the complications. Typically, a paradoxical or IRIS reaction that is not severe should be treated symptomatically with nonsteroidal anti-inflammatory agents without a change in anti-TB treatment or ART **(BIII).** Approaches to the management of severe reactions (e.g., high fever, airway compromise from enlarging lymph nodes, enlarging serosal fluid collections, increased intracranial pressure [ICP], or sepsis syndrome) have not been studied but might require invasive interventions such as surgical decompression, and although no specific treatment is recommended for severe reactions, improvement has been observed with the use of prednisone or methylprednisolone used at a dose of approximately 1 mg/kg body weight gradually reduced after 1–2 weeks **(BIII)** (*48*)**.**

Management of Treatment Failure

Drug-resistant TB continues to be a substantial clinical and public health problem. Predisposing factors include cavitary disease with a large bacillary load, use of an inadequate drug regimen, or a combined failure of both the patient and the provider to ensure compliance with the prescribed regimen (*277*). Ongoing transmission of drug-resistant strains is a source of new drug-resistant cases (*355*). The recommended treatment for drug-resistant TB is the same for HIV-infected as for non-HIV-infected patients **(AII)** (*277,355*). The optimal duration of treatment for highly resistant strains has not been established.

For patients with *M. tuberculosis* strains resistant to INH, INH should be discontinued and the patient treated with a 6-month regimen of RIF, PZA, and EMB, which is nearly as effective as the conventional INH-containing regimen **(BII)**. A fluoroquinolone may be added for those with more severe or extensive disease **(CIII)**. Alternatively, treatment with RIF and EMB for 12 months can be used, with PZA added during at least the initial 2 months **(BII).**

Treatment regimens for TB disease caused by RIF mono-resistant strains are less effective, and patients infected with these strains are at increased risk for relapse and treatment failure. A minimum of 12–18 months of treatment with INH, EMB, and a fluoroquinolone (e.g., levofloxacin, moxifloxacin) with PZA administered during the first 2 months is recommended **(BIII)**. An injectable agent (e.g., amikacin or capreomycin) might be included in the first 2–3 months for patients with RIF mono-resistance and severe or extensive disease **(CIII).**

Patients with *M. tuberculosis* resistant to both INH and RIF (MDR-TB) are at high risk for treatment failure and further acquired resistance and require close follow-up during and after treatment. Treatment regimens for MDR-TB should be individualized based on drug-resistance test results, relative activities of available anti-TB agents, the extent of disease, potential interaction with ARVs, and presence of other comorbid conditions **(AIII).** Treatment regimens should consist of at least four effective drugs **(AIII)** (*277,355*). The management of MDR-TB is complex and should be undertaken only by an experienced specialist or in close consultation with specialized treatment centers **(AIII).**

Reports of highly resistant *M. tuberculosis* strains have occurred during the past two decades (*356,357,358, 359,360*). The emergence of *M. tuberculosis* with extensive drug resistance was first reported on a global level in 2006 (*361*). The WHO Emergency Global Task Force on XDR-TB has defined XDR-TB as resistance to at least INH and RIF among the first-line anti-TB drugs, and resistance to any fluoroquinolone and at least one of three injectable second-line drugs (kanamycin, amikacin, capreomycin) (*362*). XDR-TB has been reported in the United States and every region of the world (*363–365*). Community transmission of XDR-TB and a high and rapid mortality rate among HIV-infected patients with XDR-TB

have been documented in South Africa (*366*). Poor TB treatment outcomes and high mortality among HIV-infected persons with XDR-TB also have been reported from New York City (*367*). Patients with *M. tuberculosis* resistant to RIF or any two first-line drugs should be tested for susceptibility to a full panel of anti-TB drugs **(BIII).** Repeat drug-susceptibility testing should be considered for HIV-infected patients with MDR-TB who are not responding to treatment to rapidly identify drug resistance that occurs during treatment **(BIII).** Contact investigation and strict infection- control precautions should be implemented according to national guidelines **(BIII)** (*368*). The management of XDR-TB should be undertaken only by an experienced specialist in close consultation with specialized treatment centers **(AIII).**

Preventing Recurrence

For patients with a low ongoing risk for exposure and transmission of *M. tuberculosis* infection, chronic suppressive therapy after successful completion of a recommended treatment regimen for LTBI or active TB is unnecessary **(DII).** However, recurrence of TB disease can result from either endogenous relapse or exogenous reinfection. Even in low TB burden countries, reinfection is a risk for HIV-infected residents of institutions that pose an ongoing high risk for exposure to *M. tuberculosis* (e.g., prisons, jails, and homeless shelters) (*282,283*). Recurrence of TB disease is also substantially increased in HIV-infected persons in geographic areas with a high TB burden (*344,369–375*). In these settings, treatment of LTBI resulting from presumed reinfection among persons previously treated for TB has been documented to reduce recurrence of TB disease (*370,372,376*). The reported incidence of TB disease for persons immigrating to the United States from settings with high TB burden (especially Sub-Saharan Africa and Asia) who have been in the United States <1 year is often greater than the estimated case rate in their country of origin (*377*). Recent molecular epidemiology studies suggest that the majority of TB cases among foreign-born persons in the United States are caused by or related to activation of latent infection (*377–381*). These findings suggest that recent immigrants might be at high risk for recent infection or reinfection in their countries of origin. Close monitoring of recent immigrants at such risk is necessary.

Special Considerations During Pregnancy

HIV-infected pregnant women who do not have documentation of a negative TST result during the preceding year should be tested during pregnancy. The frequency of anergy is not increased during pregnancy, and routine anergy testing for HIV-1-infected pregnant women is not recommended (*382–385*). No data are available on the performance of the IGRAs for diagnosis of LTBI in pregnant women.

The diagnostic evaluation for TB disease in pregnant women is the same as for nonpregnant adults. Chest radiographs with abdominal shielding result in minimal fetal radiation exposure. An increase in pregnancy complications and undesirable outcomes (including preterm birth), low birthweight, and intrauterine growth retardation might be observed among pregnant women with either pulmonary or extrapulmonary TB not confined to the lymph nodes, especially when treatment is not begun until late in pregnancy (*382–389*). Congenital TB infection of the infant might occur but appears to be rare (390).

Treatment of TB disease for pregnant women should be the same as for nonpregnant women, but with attention given to the following considerations **(BIII):**

- Although INH is not teratogenic in animals or humans, hepatotoxicity caused by INH might occur more frequently in pregnancy and the postpartum period (*391*). Monthly monitoring of liver transaminases during pregnancy and the postpartum period is recommended (**CIII**).
- RIF is not teratogenic in humans. Because of a potential increased risk for RIF-related hemorrhagic disease among neonates born to women who receive anti-TB therapy during pregnancy, prophylactic vitamin K, in a single 10 mg dose, should be administered to the neonate (**BIII**).
- PZA is not teratogenic among animals. Experience is limited with use in human pregnancy. Although WHO and the International Union Against Tuberculosis and Lung Diseases (*392,393*) have made recommendations for the routine use of PZA in pregnant women, it has not been recommended for general use during pregnancy in the United States because data characterizing its effects in this setting are limited (*394*). If PZA is not included in the initial treatment regimen, the minimum duration of TB therapy should be 9 months. The decision regarding whether to include PZA for treatment should be made after consultation among obstetricians, TB specialists, and women, taking into account gestational age and likely susceptibility pattern of the infecting strain (**CIII**).
- EMB is teratogenic among rodents and rabbits at doses that are much higher than those used among humans. No evidence of teratogenicity has been observed among humans. Ocular toxicity has been reported among adults taking EMB, but changes in visual acuity have not been detected in infants born after exposure in utero.

Experience with using the majority of the second-line drugs for TB during pregnancy is limited. MDR-TB in pregnancy should be managed in consultation with a specialist. Therapy should not be withheld because of pregnancy **(AIII).** The fol-

lowing concerns should be considered when selecting second-line anti-TB drugs for use among pregnant women:

- Streptomycin use has been associated with a 10% rate of VIII nerve toxicity in infants exposed in utero; its use during pregnancy should be avoided if possible (**DIII**).
- Hearing loss has been detected in approximately 2% of children exposed to long-term kanamycin therapy in utero; like streptomycin, this agent should typically be avoided if possible (**DIII**). The fetus is at a theoretical risk for ototoxicity with in utero exposure to amikacin and capreomycin, but this risk has not been documented and these drugs might be alternatives when an aminoglycoside is required for treatment of MDR-TB (**CIII**).
- Because arthropathy has been noted in immature animals exposed in utero to quinolones, quinolones are typically not recommended for pregnant women and among children aged <18 years (**CIII**). However, >400 cases of quinolone use in human pregnancies have been reported to various pregnancy registries, and use has not been associated with human arthropathy or birth defects after in utero exposure. Thus, quinolones can be used in pregnancy for drug-resistant TB, if they are required on the basis of susceptibility testing (**CIII**) *(395)*.
- Para-aminosalicylic acid (PAS) is not teratogenic among rats or rabbits *(394)*. In one study, a possible increase in limb and ear anomalies was reported among 143 infants delivered by woman who were exposed during the first trimester of their pregnancies (*396*). No specific pattern of defects and no increase in rate of defects have been detected among subjects in other human studies, indicating that this agent can be used with caution if needed (**CIII**).
- Ethionamide has been associated with an increased risk for several anomalies among mice, rats, and rabbits after high-dose exposure; no increased risk for defects was noted with doses similar to those used among humans, but experience is limited with use during human pregnancy. Thus, ethionamide should be avoided unless its use is necessary (**CIII**).
- No data are available from animal studies or reports of cycloserine use in humans during pregnancy.

If LTBI is diagnosed during pregnancy and active TB has been ruled out, treatment should be initiated during pregnancy whenever possible **(BIII)**. If the woman is receiving ART only for prophylaxis of perinatal HIV transmission and will stop ARVs after delivery, deferral of treatment for LTBI until after delivery or use of a triple nucleoside regimen to allow use of RIF is reasonable. For women who require long-term ART for their own health, initiation of INH prophylaxis during pregnancy is recommended **(BIII)**.

ART is indicated for all pregnant women either for treatment of maternal infection, or if not indicated for maternal therapy, for prevention of perinatal transmission of HIV (*397*). Pregnant women on ART who have a diagnosis of active TB should have their ARV regimens adjusted as needed to accommodate their TB drugs. For women whose diagnosis includes concurrent active TB and HIV infection during pregnancy, TB therapy should be initiated immediately and ART should be initiated as soon as possible thereafter, usually according to the principles described for nonpregnant adults. Efavirenz use is not recommended during the first trimester because of 1) substantial CNS and cleft defects seen in cynomolgous monkeys treated in the first trimester with efavirenz at doses similar to those used in humans and 2) because of case reports of neural tube defects in humans after first-trimester exposure. Efavirenz can be used after the first trimester, if indicated, to avoid drug interactions between anti-TB drugs and PIs. Initiation of nevirapine is not recommended for women with $CD4^+$ counts >250 cells/μL because of an increased risk for potentially fatal liver toxicity. For women who require ART strictly for prophylaxis of perinatal HIV transmission, use of a triple nucleoside regimen, including abacavir, could be considered to avoid interactions with TB drugs.

Disseminated *Mycobacterium avium* Complex Disease

Epidemiology

Organisms of the *Mycobacterium avium* complex (MAC) are ubiquitous in the environment (*398–400*). *M. avium* is the etiologic agent in >95% of patients with AIDS who acquire disseminated MAC disease (*398,401–406*). An estimated 7%–12% of adults have been previously infected with MAC, although rates of disease vary in different geographic locations (*398,402,405,406*). Although epidemiologic associations have been identified, no environmental exposure or behavior has been consistently linked to a subsequent risk for developing MAC disease.

The mode of transmission is thought to be through inhalation, ingestion, or inoculation via the respiratory or gastrointestinal tract. Household or close contacts of those with MAC disease do not appear to be at increased risk for disease, and person-to-person transmission is unlikely.

In the absence of effective ART or chemoprophylaxis in those with AIDS-associated immunosuppression, the incidence of disseminated MAC disease is 20%–40% (*407,408*). For persons with a $CD4^+$ count <100 cells/μL who are receiving effective prophylaxis or have responded to ART with a sustained increase in $CD4^+$ count to levels >100–200 cells/μL, the overall incidence has been estimated at 2 cases per 100

person-years. MAC disease typically occurs among persons with CD4+ counts <50 cells/μL. Other factors that are associated with increased susceptibility to MAC disease are high plasma HIV RNA levels (>100,000 copies/mL), previous OIs, previous colonization of the respiratory or gastrointestinal tract with MAC, and reduced in vitro lymphoproliferative immune responses to *M. avium* antigens, possibly reflecting defects in T-cell repertoire.

Clinical Manifestations

In persons with AIDS not on ART, MAC disease is typically a disseminated multi-organ infection (*409–412*). Early symptoms might be minimal and might precede detectable mycobacteremia by several weeks. Symptoms include fever, night sweats, weight loss, fatigue, diarrhea, and abdominal pain (*402*).

Localized manifestations of MAC disease have been reported most frequently among persons who are receiving and have responded to ART. Localized syndromes include cervical or mesenteric lymphadenitis, pneumonitis, pericarditis, osteomyelitis, skin or soft tissue abscesses, genital ulcers, or CNS infection.

Laboratory abnormalities particularly associated with disseminated MAC disease include anemia (often out of proportion to that expected for the stage of HIV disease) and elevated liver alkaline phosphatase (*398,399,401–408,413,414*). Hepatomegaly, splenomegaly, or lymphadenopathy (paratracheal, retroperitoneal, para-aortic, or less commonly peripheral) might be identified on physical examination or by radiographic or other imaging studies. Other focal physical findings or laboratory abnormalities might occur in the context of localized disease.

IRIS, initially characterized by focal lymphadenitis with fever, has subsequently been recognized as a systemic inflammatory syndrome with signs and symptoms that are clinically indistinguishable from active MAC infection. Its occurrence with MAC disease is similar to IRIS or paradoxical reactions observed with TB disease (*415–418*). Bacteremia is absent. The syndrome has been described among patients with subclinical ("unmasking IRIS") or established MAC disease and advanced immunosuppression who begin ART and have a rapid and marked increase in CD4+ count (≥100 cells/μL). As with TB, the syndrome might be benign and self-limited or might result in severe unremitting symptoms that are improved with the use of systemic anti-inflammatory therapy or corticosteroids in doses similar to those described for TB-associated IRIS.

Diagnosis

A confirmed diagnosis of disseminated MAC disease is based on compatible clinical signs and symptoms coupled with the isolation of MAC from cultures of blood, lymph node, bone marrow, or other normally sterile tissue or body fluids (*408,411,419,420*). Species identification should be performed using specific DNA probes, high performance liquid chromatography, or biochemical tests.

Other ancillary studies provide supportive diagnostic information, including AFB smear and culture of stool or tissue biopsy material, radiographic imaging, or other studies aimed at isolation of organisms from focal infection sites.

Preventing Exposure

MAC organisms commonly contaminate environmental sources (e.g., food and water). Available information does not support specific recommendations regarding avoidance of exposure.

Preventing Disease

Initiating Primary Prophylaxis

HIV-infected adults and adolescents should receive chemoprophylaxis against disseminated MAC disease if they have a CD4+ count of <50 cells/μL **(AI)**. Azithromycin (*421*) or clarithromycin (*399,422*) are the preferred prophylactic agents **(AI)**. The combination of clarithromycin and rifabutin is no more effective than clarithromycin alone for chemoprophylaxis, is associated with a higher rate of adverse effects than either drug alone, and should not be used **(EI)** (*399*). The combination of azithromycin with rifabutin is more effective than azithromycin alone; however, the additional cost, increased occurrence of adverse effects, potential for drug interactions, and absence of a survival difference compared with azithromycin alone do not warrant a routine recommendation for this regimen **(CI)** (*421*). Azithromycin and clarithromycin also each confer protection against respiratory bacterial infections **(BII)**. If azithromycin or clarithromycin cannot be tolerated, rifabutin is an alternative prophylactic agent for MAC disease, although drug interactions might complicate the use of this agent **(BI)** (*423,424*). Before prophylaxis is initiated, disseminated MAC disease should be ruled out by clinical assessment, which might include obtaining a blood culture for MAC. Because treatment with rifabutin could result in RIF resistance among persons who have active TB, active TB also should be excluded before rifabutin is used for prophylaxis.

Although detecting MAC organisms in the respiratory or gastrointestinal tract might predict disseminated MAC infection, no data are available regarding efficacy of prophylaxis with clarithromycin, azithromycin, rifabutin, or other drugs among asymptomatic patients harboring MAC organisms at these sites in the presence of a negative blood culture. Therefore, routine screening of respiratory or gastrointestinal specimens for MAC is not recommended **(DIII)**.

Discontinuing Primary Prophylaxis

Primary MAC prophylaxis should be discontinued among adult and adolescent patients who have responded to ART with an increase in $CD4^+$ counts to >100 cells/μL for ≥3 months **(AI)**. Two randomized, placebo-controlled trials and observational data have demonstrated that such patients can discontinue primary prophylaxis with minimal risk for acquiring MAC disease (*126,425–428*). Discontinuing primary prophylaxis among patients who meet these criteria is recommended to reduce pill burden, the potential for drug toxicity, drug interactions, selection of drug-resistant pathogens, and cost. Primary prophylaxis should be reintroduced if the $CD4^+$ count decreases to <50 cells/μL **(AIII)**.

Treatment of Disease

Initial treatment of MAC disease should consist of two or more antimycobacterial drugs to prevent or delay the emergence of resistance **(AI)** (*400,405,406,429–436*). Clarithromycin is the preferred first agent **(AI);** it has been studied more extensively than azithromycin in patients with AIDS and appears to be associated with more rapid clearance of MAC from the blood (*400,429,431,435–437*). However, azithromycin can be substituted for clarithromycin when drug interactions or clarithromycin intolerance preclude the use of clarithromycin **(AII)**. Testing MAC isolates for susceptibility to clarithromycin or azithromycin is recommended for all patients **(BIII)** (*438,439*)**.**

EMB is the recommended second drug **(AI)**. Some clinicians add rifabutin as a third drug **(CI)**. One randomized clinical trial demonstrated that the addition of rifabutin to the combination of clarithromycin and EMB improved survival, and in two randomized clinical trials, this approach reduced emergence of drug resistance (*400,431*) in persons with AIDS and disseminated MAC disease. These studies were completed before the availability of effective ART. The addition of a third or fourth drug should be considered in persons with advanced immunosuppression ($CD4^+$ count <50 cells/μL), high mycobacterial loads (>2 $\log_{10}$ colony forming units/mL of blood), or in the absence of effective ART, settings in which mortality is increased and emergence of drug resistance is most likely **(CIII)**. On the basis of data in non-HIV-infected patients, the third or fourth drug might include an injectable agent such as amikacin or streptomycin **(CIII)** (*438*)**.**

Patients who have disseminated MAC disease and have not been treated previously with or are not receiving effective ART should generally typically have ART withheld until after the first 2 weeks of antimycobacterial therapy have been completed to reduce risk for drug interactions, pill burden, and complications associated with the occurrence of IRIS **(CIII)**. If ART has already been instituted, it should be continued and optimized unless drug interactions preclude the safe concomitant use of antiretroviral and antimycobacterial drugs **(CIII)**.

Monitoring and Adverse Events, Including Immune Reconstitution Inflammatory Syndrome (IRIS)

A repeat blood culture for MAC should be obtained 4–8 weeks after initiating antimycobacterial therapy only for patients who fail to have a clinical response to their initial treatment regimen. Improvement in fever and a decline in quantity of mycobacteria in blood or tissue can be expected within 2–4 weeks after initiation of appropriate therapy; however, for those with more extensive disease or advanced immunosuppression, clinical response might be delayed.

Adverse effects with clarithromycin and azithromycin include nausea, vomiting, abdominal pain, abnormal taste, and elevations of liver transaminase levels or hypersensitivity reactions. Doses of clarithromycin >1 g/day for treatment of disseminated MAC disease have been associated with increased mortality and should not be used **(EI)** (*440*). Rifabutin doses of ≥450 mg/day have been associated with higher risk for adverse drug interactions when used with clarithromycin or other drugs that inhibit cytochrome P450 isoenzyme 3A4 and might be associated with a higher risk for experiencing uveitis, arthralgias, or other adverse drug reactions (*441,442*).

Persons who develop moderate to severe symptoms typical of IRIS during ART, should receive initial treatment with nonsteroidal, anti-inflammatory agents **(CIII)**. If IRIS symptoms do not improve, short-term (4–8 weeks) systemic corticosteroid therapy, in doses equivalent to 20–40 mg of oral prednisone daily, has been successful in reducing symptoms and morbidity **(CIII)** (*416,443,444*).

Rifabutin should not be administered to patients receiving certain PIs and NNRTIs because the complex interactions have been incompletely studied and the clinical implications of those interactions are unclear (*423,424*). PIs can increase clarithromycin levels, but no recommendation to adjust the dose of either clarithromycin or PIs can be made on the basis of existing data. Efavirenz can induce metabolism of clarithromycin. This can result in reduced serum concentration of clarithromycin but increased concentration of the 14-OH active metabolite of clarithromycin. Although the clinical significance of this interaction is unknown, the efficacy of clarithromycin for MAC prophylaxis could be reduced because of this interaction. Azithromycin metabolism is not affected by the cytochrome P450 (CYP450) system; azithromycin can be used safely in the presence of PIs or NNRTIs without concerns of drug interactions.

Management of Treatment Failure

Treatment failure is defined by the absence of a clinical response and the persistence of mycobacteremia after 4–8 weeks of treatment. Repeat testing of MAC isolates for susceptibility to clarithromycin or azithromycin is recommended for patients who relapse after an initial response. The majority of patients who experience failure of clarithromycin or azithromycin primary prophylaxis in clinical trials had isolates susceptible to these drugs at the time MAC disease was detected (*400,405,406,429,445,446*).

Because the number of drugs with demonstrated clinical activity against MAC is limited, results of susceptibility testing should be used to construct a new multi-drug regimen. The regimen should consist of at least two new drugs not used previously, to which the isolate is susceptible and selected from among the following: EMB, rifabutin, amikacin, or a quinolone (moxifloxacin, ciprofloxacin, or levofloxacin), although data supporting a survival or microbiologic benefit when these agents are added have not been compelling **(CIII)** (*33,405,406,430-434,437,447–450*). On the basis of data related to non-HIV-infected patients being treated for MAC, an injectable agent such as amikacin or streptomycin should be considered **(CIII)** (*438*)**.** Whether continuing clarithromycin or azithromycin despite resistance provides additional benefit is unknown. Clofazimine should not be used because randomized trials have demonstrated lack of efficacy and an association with increased mortality **(EII)** (*430,432,448*)**.** Other second-line agents (e.g., ethionamide, thiacetazone [not available in the United States], or cycloserine) have been anecdotally combined with clarithromycin and azithromycin as salvage regimens. However, their role in this setting is not well defined. Among patients whose initial treatment for MAC disease has not been successful or who have antimycobacterial drug-resistant MAC disease, optimizing ART is an important adjunct to second-line or salvage therapy for MAC disease **(AIII)**.

Adjunctive treatment of MAC disease with immunomodulators has not been thoroughly studied, and data are insufficient to support a recommendation for use **(DIII)**.

Preventing Recurrence

Adult and adolescent patients with disseminated MAC disease should receive lifelong secondary prophylaxis (chronic maintenance therapy) **(AII)**, unless immune reconstitution occurs as a result of ART (*425,426*).

Discontinuing Secondary Prophylaxis (Chronic Maintenance Therapy)

Patients are at low risk for recurrence of MAC when they have completed a course of ≥12 months of treatment for MAC, remain asymptomatic with respect to MAC signs and symptoms, and have a sustained increase (e.g., >6 months) in their $CD4^+$ counts to >100 cells/μL after ART. Although the numbers of patients who have been evaluated remain limited and recurrences could occur, based on the limited number of patients who have been evaluated and the inferences from more extensive data indicating the safety of discontinuing secondary prophylaxis for other OIs, discontinuing chronic maintenance therapy is reasonable **(BII)** (*121,426,434,451*). Secondary prophylaxis should be reintroduced if the $CD4^+$ count decreases to <100 cells/μL **(AIII)**.

Special Considerations During Pregnancy

Chemoprophylaxis for MAC disease should be administered to pregnant women the same as for nonpregnant women and adolescents **(AIII)**. Because of an increased risk for birth defects evident in certain animal studies, clarithromycin is not recommended as the first-line agent for prophylaxis or treatment of MAC in pregnancy **(DIII)**. Two studies, each with slightly more than 100 women with first-trimester exposure to clarithromycin, did not demonstrate an increase in or specific pattern of defects, although an increased risk for spontaneous abortion was noted in one study (*452,453*). Azithromycin did not produce defects in animal studies, but experience for use in humans during the first trimester is limited. Azithromycin is recommended for primary prophylaxis in pregnancy **(BIII)**. For secondary prophylaxis (chronic maintenance therapy), azithromycin plus EMB are the preferred drugs **(BIII)**.

Diagnostic considerations and indications for treatment of pregnant women are the same as for nonpregnant women. On the basis of animal data discussed previously, azithromycin is preferred over clarithromycin as the second agent with EMB **(BIII)**. Use of EMB should minimize concerns regarding drug interactions, allowing initiation of ART as soon as possible during pregnancy to decrease the risk for perinatal transmission of HIV. Pregnant women whose treatment failed on their primary regimen should be managed in consultation with infectious disease and obstetrical specialists.

Bacterial Respiratory Disease

Epidemiology

Bacterial pneumonia is a common cause of HIV-associated morbidity. The incidence of bacterial pneumonia among HIV-infected persons is greater than that in the noninfected population (*454*). In the precombination ART era, the Pulmonary Complications of HIV Infection Study reported that the incidence of bacterial pneumonia ranged was 3.9–7.3 episodes per 100 person-years (*455*). In the current era, the incidence of bacterial pneumonia in HIV-infected persons has declined (*4,456,457*).

Bacterial pneumonia might be the first manifestation of underlying HIV infection and can occur at any stage of HIV disease and at any CD4+ count. The high rates of bacterial pneumonia in HIV-infected persons probably result from multiple factors, including qualitative B-cell defects that impair ability to produce pathogen-specific antibody, impaired neutrophil function or numbers or both, and factors (e.g., injection drug use) that are associated with underlying HIV infection. Risk factors associated with an increased risk for bacterial pneumonia, include low CD4+ count, injection-drug use, and cigarette smoking (*454*).

Similar to persons without HIV infection, *Streptococcus pneumoniae* and *Haemophilus* species are the most frequently identified causes of community-acquired bacterial pneumonia in HIV-infected persons (*458–464*). Similar to the noninfected population, drug-resistant *Streptococcus pneumoniae* is an increasing concern and is associated with increased mortality (*465*).

Although atypical bacterial pathogens such as *Legionella pneumophila*, *Mycoplasma pneumoniae*, and *Chlamydophila* species have been reported as infrequent causes of community-acquired bacterial pneumonia in HIV-infected persons (*461,466*), they are important considerations in decisions regarding antibiotic treatment.

In contrast to the noninfected population, *Pseudomonas aeruginosa* and *Staphylococcus aureus* are both reported as community-acquired pathogens with an increased frequency among persons with HIV infection (*462,467*).

Compared with persons without HIV infection, HIV-infected persons have an increased incidence of bacteremia accompanying pneumonia, especially if they are infected with *S.pneumoniae*. (*468–470*). In one study, the estimated rate of pneumococcal bacteremia (9.4 cases per 1,000 patient-years) in AIDS patients was approximately 100-fold greater than in HIV-uninfected historical controls (*468*).

Bacterial pneumonia is associated with an increased mortality among HIV-infected persons (*462,471,472*). Among HIV-infected persons with community-acquired bacterial pneumonia, a prospective, multicenter study documented that a CD4+ count <100 cells/μL, radiographic progression of disease, and the presence of shock were independent predictors of increased mortality (*473*). In this study, multilobar infiltrates, cavitary infiltrates, and pleural effusion at baseline were all independent predictors of radiographic progression of HIV.

Clinical Manifestations

The clinical and radiographic presentation of bacterial pneumonia in HIV-infected persons is similar to that in persons without HIV infection. Persons with pneumonias caused by *Streptococcus pneumoniae* and *Haemophilus* species characteristically have an acute onset (3–5 days) of symptoms, including fevers, chills, rigors, chest pain, cough productive of purulent sputum, and dyspnea (*92*). On examination of vital signs, patients are often febrile. The presence of tachycardia or hypotension is an indicator of the systemic inflammatory response syndrome (SIRS). Tachypnea and decreased arterial oxygen saturation indicate moderate-to-severe pneumonia and clinicians should strongly consider hospitalizing such patients.

Persons with bacterial pneumonia typically have evidence of focal consolidation and/or pleural effusion on lung examination, as contrasted to persons with PCP, in which the lung examination is often normal or, if abnormal, reveals inspiratory crackles.

The white blood cell (WBC) count is usually elevated in persons with bacterial pneumonia. In persons with advanced HIV disease, the elevation might be relative to the persons's baseline WBC. A left shift also might be present.

Persons with bacterial pneumonia characteristically exhibit unilateral, focal, segmental, or lobar consolidation on chest radiograph. However, the frequency of these typical radiographic findings might depend on the underlying bacterial pathogen. HIV-infected persons might present with multifocal or multilobar involvement and with parapneumonic effusions more frequently than persons without HIV infection (*474*).

Diagnosis

Guidelines for the management of community-acquired pneumonia (CAP) in persons without HIV infection also apply to HIV-infected persons (*475*). Persons with clinical symptoms and signs suggestive of CAP should have a chest radiograph. When available, previous radiographs should be reviewed to assess for the presence of new findings. The clinical diagnosis of bacterial pneumonia requires a demonstrable infiltrate.

Given the increased incidence of *Mycobacterium tuberculosis* in HIV-infected persons, the diagnosis of TB should always be suspected in HIV-infected persons who have pneumonia. Those persons with a clinical and radiographic evidence suggestive of TB should be managed as potential TB (e.g., respiratory isolation if hospitalized), and three sputum specimens should be obtained for AFB smear and culture. Dual therapy for both bacterial pneumonia and TB is appropriate for patients for whom both of these diagnoses are considerations and where diagnostic studies are undertaken.

Standard recommendations for routine testing for bacterial pneumonia remain controversial (*475*). Usually, the differential diagnosis of pneumonia in HIV-infected persons is broad and a confirmed microbiologic diagnosis might allow clinicians to target the specific pathogen and to discontinue broad spectrum antibiotic therapy and/or empiric therapy that targets nonbacterial pathogens (e.g., empiric PCP therapy). The increased incidence of bacteremia in HIV-infected persons (especially

at low CD4+ count) and the high specificity of blood cultures argue for their collection in HIV-infected persons. Although the low sensitivity of sputum and blood cultures and the infrequency that these results alter clinical management in HIV-uninfected patients with CAP argue against their routine collection, patients with HIV infection are at increased risk for infection with drug-resistant *Streptococcus pneumococci* (drug-resistant *S. pneumoniae*) and identification of this organism could lead to changes in management.

HIV-infected persons with suspected CAP should undergo investigation for specific pathogens that would significantly alter standard (empirical) management decisions when the presence of such pathogens is suspected on the basis of epidemiologic, clinical, or radiologic clues. *Pseudomonas aeruginosa* should be considered in HIV-infected persons with advanced HIV disease (i.e., CD4+ count ≤50 cells/μL); those with pre-existing lung disease (i.e., bronchiectasis); underlying neutropenia, corticosteroid therapy, or severe malnutrition; those who have been hospitalized within 90 days or reside in a health-care facility or nursing home; and those on chronic hemodialysis. Given the frequency of cavitary infiltrates in persons with *P. aeruginosa*, this radiographic finding should also prompt an investigation for this pathogen. *Staphylococcus aureus* should be considered in persons with recent viral (or influenza) infection; history of injection-drug use; or severe, bilateral, necrotizing pneumonia.

Routine diagnostic tests to identify an etiologic diagnosis are optional for persons with CAP who are well enough to be treated as outpatients, especially true if microbiologic studies cannot be performed promptly.

A pretreatment expectorated sputum specimen for Gram stain and culture and two blood cultures should be obtained from persons with CAP who are hospitalized, especially if intensive care is required. Gram stain and culture of expectorated sputum should be performed only if a good-quality specimen can be obtained and quality performance measures for collection, transport, and processing of samples can be met. Correlation of the sputum culture with the Gram stain can help in the interpretation of sputum culture data. For intubated patients, an endotracheal aspirate sample should be obtained. In addition to the above tests, urinary antigen tests for *Legionella pneumophila* and *Streptococcus pneumoniae* should be considered.

Diagnostic thoracentesis should be considered in any person with pleural effusion, especially if a concern exists for accompanying empyema, and a therapeutic thoracentesis should be performed to relieve respiratory distress secondary to a moderate- to large-sized effusion.

Preventing Exposure

No effective means exist to reduce exposure to *Streptococcus pneumoniae* and *Haemophilus influenzae*, which are common in the community.

Preventing Disease

HIV-infected adults and adolescents who have a CD4+ count of >200 cells/μL should be administered a single dose of 23-valent polysaccharide pneumococcal vaccine (PPV) unless they have received this vaccine during the previous 5 years **(AII)** (*157,476–479*). One randomized placebo-controlled trial of pneumococcal vaccine in Africa paradoxically determined that an increased risk for pneumonia was associated with vaccination (*480*). Follow-up of this cohort confirmed the increase in pneumonia in vaccinated subjects but also reported a decrease in all-cause mortality (*481*). In contrast, multiple observational studies of pneumococcal vaccine in the United States have reported benefits from vaccination (*157,476–479,482*). Studies also have documented that vaccination is associated with a lower risk for pneumococcal bacteremia (*482,483*). The majority of HIV specialists believe that the potential benefit of pneumococcal vaccination in the United States outweighs the risk.

HIV-infected adults and adolescents who have a CD4+ count of <200 cells/μL can be offered PPV **(CIII)**. Clinical evidence has not confirmed efficacy in this group, but evidence documents the benefit for those who also start ART (*482*). Revaccination can be considered for persons who were initially vaccinated when their CD4+ counts were <200 cells/μL and whose CD4+ counts have increased to >200 cells/μL in response to ART **(CIII)**.

The duration of the protective effect of primary pneumococcal vaccination is unknown; revaccination every 5 years may be considered **(CIII)** (*479*). No evidence confirms clinical benefit from revaccination. Nevertheless, the recommendation to vaccinate is increasingly pertinent because of the increasing incidence of invasive infections with drug-resistant (including TMP-SMX-, macrolide-, and ß-lactam-resistant) strains of *S. pneumoniae*.

The incidence of *H. influenzae* type b (Hib) infection among HIV-infected adults is low. Therefore, Hib vaccine is not usually recommended for adult use **(DIII)**.

Several factors are associated with a decreased risk for bacterial pneumonia, including the use of combination ART and TMP-SMX used for PCP prophylaxis (*472*). The use of antimicrobial prophylaxis to prevent bacterial pneumonia has been explored. In many studies, TMP-SMX, when administered daily for PCP prophylaxis, reduces the frequency of bacterial respiratory infections (*30*, *114,454*). This should be considered in selecting an agent for PCP prophylaxis **(AII)**. However,

indiscriminate use of this drug (when not indicated for PCP prophylaxis or other specific reasons) might promote development of TMP-SMX-resistant organisms. Thus, TMP-SMX should not be prescribed solely to prevent bacterial respiratory infection **(DIII)**. Similarly, clarithromycin administered daily or azithromycin administered weekly for MAC prophylaxis might be effective in preventing bacterial respiratory infections (*421,484*). This should be considered in selecting an agent for prophylaxis against MAC (**BII**). However, these drugs should not be prescribed solely for preventing bacterial respiratory infection **(DIII)**.

An absolute neutrophil count that is depressed because of HIV disease or drug therapy is associated with an increased risk for bacterial infections, including pneumonia. To reduce the risk for such bacterial infections, health-care providers might consider taking steps to reverse neutropenia, either by stopping myelosuppressive drugs **(CII)** or by administering granulocyte-colony stimulating factor (G-CSF) **(CII)**.

Modifiable factors associated with an increased risk for bacterial pneumonia include smoking cigarettes and other drugs, injection-drug use (IDU), and alcohol use (*138,454,485,486*). Clinicians should encourage cessation of these behaviors, although no data exist to indicate that cessation decreases risk **(CIII)**.

Inactivated influenza vaccine should be administered annually to all HIV-infected persons during influenza season **(AIII)**. This recommendation is pertinent to prevention of bacterial pneumonia, which might occur as a complication of influenza illness. Live attenuated influenza vaccine is contraindicated for HIV-infected persons **(EIII)**.

Treatment of Disease

The principles of the treatment of community-acquired bacterial pneumonia are the same for HIV-infected persons as for HIV-uninfected persons (*475*). Usually, collection of specimens for microbiologic studies should be performed before the initiation of antibiotic therapy. However, antibiotic therapy should be administered promptly, without waiting for the results of diagnostic testing.

An assessment of disease severity and arterial oxygenation should be performed in all persons with pneumonia. Noninvasive measurement of arterial oxygen saturation via pulse oximetry is an appropriate screening test. However, ABG analysis is indicated for persons with evidence of hypoxemia suggested by noninvasive assessment and for persons with tachypnea and/or respiratory distress. Criteria that were developed to assess CAP disease severity in HIV-uninfected persons have been found to be valid for HIV-infected persons (*473*). Unlike recommendations for CAP therapy in non-HIV patients, no HIV-infected patient should receive macrolide monotherapy because of the increased risk for drug-resistant *Streptococcus pneumoniae* in the HIV-infected patient.

Outpatient Treatment

HIV-infected persons who are being treated as outpatients should receive an oral beta-lactam plus an oral macrolide **(AII).** Preferred beta-lactams are high-dose amoxicillin and amoxicillin-clavulanate; cefpodoxime and cefuroxime are alternatives. Preferred macrolides are azithromycin and clarithromycin. Oral doxycycline is an alternative to the macrolide **(CIII)**.

For persons who are allergic to penicillin or who have received a beta-lactam within the previous 3 months, an oral respiratory fluoroquinolone (moxifloxacin, levofloxacin [750 mg/day], or gemifloxacin) should be used **(AII)**. Respiratory fluoroquinolones are active against *Mycobacterium tuberculosis.* Thus, persons with TB who are treated with fluoroquinolone monotherapy might respond initially, but this response might be misleading, might delay the diagnosis of TB and the initiation of appropriate multi-drug therapy, and might increase the risk for transmission of TB. Thus, fluoroquinolones should be used with caution in patients in whom TB is suspected but who are not being treated with concurrent standard four-drug TB therapy. Because HIV-infected persons have an increased incidence of TB and the presentation of TB can be varied in HIV-infected persons, fluoroquinolones should be used only when the presentation strongly suggests bacterial pneumonia.

Increasing pneumococcal resistance rates have suggested that empirical therapy with a macrolide alone cannot be routinely recommended **(DIII)**. Patients who are receiving a macrolide for MAC prophylaxis should never receive macrolide monotherapy for empiric treatment of bacterial pneumonia.

Non-ICU Inpatient Treatment

HIV-infected persons who are being treated as inpatients should receive an IV beta-lactam plus a macrolide **(AII)**. Preferred beta-lactams are ceftriaxone, cefotaxime, or ampicillin-sulbactam. Doxycycline is an alternative to the macrolide **(CIII)**.

For persons who are allergic to penicillin or who have received a beta-lactam within the previous 3 months, an IV respiratory fluoroquinolone (moxifloxacin or levofloxacin [750 mg/day]) should be used **(AII)**. Because of the activity of fluoroquinolones against *Mycobacterium tuberculosis* and the dangers of monotherapy in persons with TB, fluoroquinolones should be used with caution in patients in whom TB is suspected but is not being treated with concurrent standard four-drug TB therapy.

Increasing pneumococcal resistance rates have suggested that empirical therapy with a macrolide alone cannot be recommended routinely **(DIII)**. Patients who are receiving a

macrolide for MAC prophylaxis should never receive macrolide monotherapy for empiric treatment of bacterial pneumonia.

ICU Treatment

Persons with severe pneumonia who require intensive care should be treated with an IV beta-lactam plus either IV azithromycin **(AII)** or an IV respiratory fluoroquinolone (moxifloxacin or levofloxacin [750 mg/day]) **(AII)**. Preferred beta-lactams are ceftriaxone, cefotaxime, or ampicillin-sulbactam.

For persons who are allergic to penicillin or who have received a beta-lactam within the previous 3 months, aztreonam plus an IV respiratory fluoroquinolone (moxifloxacin or levofloxacin [750 mg/day]) should be used **(BIII)**.

Infections with the overwhelming majority of CAP pathogens will be treated adequately by use of the recommended empirical regimens. The increased incidence of *P. aeruginosa* and *S. aureus* as a cause of CAP is the exception. These pathogens occur in specific epidemiologic patterns with distinct clinical presentations, for which empirical antibiotic coverage might be warranted. Diagnostic tests (sputum Gram stain and culture) are likely to be of high yield for these pathogens, allowing early discontinuation of empirical treatment if results are negative.

Empiric Pseudomonas aeruginosa *Treatment*

If risk factors for *Pseudomonas* infection are present, an antipneumococcal, antipseudomonal beta-lactam plus either ciprofloxacin or levofloxacin (750 mg dose) should be used **(BIII)**. Preferred beta-lactams are piperacillin-tazobactam, cefepime, imipenem, or meropenem. An antipneumococcal, antipseudomonal beta-lactam plus an aminoglycoside and azithromycin **(BIII)** or an antipneumococcal, antipseudomonal beta-lactam plus an aminoglycoside and an antipneumococcal fluoroquinolone **(BIII)** are alternatives. For persons who are allergic to penicillin or who have received a beta-lactam within the previous 3 months, aztreonam can be used in place of the beta-lactam **(BIII)**.

Empiric Staphylococcus aureus *Treatment*

If risk factors for *Staphylococcus aureus* infection, including community-acquired methicillin-resistant *S. aureus*, are present, vancomycin (possibly in combination with clindamycin) or linezolid alone should be added to the antibiotic regimen **(BIII)**.

Pathogen-Directed Therapy

When the etiology of pneumonia has been identified on the basis of reliable microbiological methods, antimicrobial therapy should be directed at that pathogen **(BIII)**.

Switch from Intravenous to Oral Therapy

For patients with CAP who begin IV antibiotic therapy, switching to oral therapy should be considered when they are improving clinically, are able to swallow and tolerate oral medications, and have intact gastrointestinal function. Suggested criteria for clinical stability include oral temperature <37.8 °C, heart rate <100 beats/minute, respiratory rate <24 breaths/minute, systolic blood pressure ≥90 mm Hg, and room air oxygen saturation >90% or partial pressure of oxygen in arterial blood (PaO2) >60 mm Hg (475).

Monitoring and Adverse Events, Including Immune Reconstitution Inflammatory Syndrome (IRIS)

The clinical response to appropriate antimicrobial therapy is similar in HIV-infected and non-HIV-infected persons (*487*). A clinical response (i.e., a reduction in fever and improvement in respiratory symptoms, physical findings, and laboratory studies) is typically observed within 48–72 hours after the initiation of appropriate antimicrobial therapy. Usually, radiographic improvement might lag behind clinical improvement. If a patient has progressive pneumonia in spite of therapy, leading to severe CAP, adjunctive therapy with corticosteroids might be appropriate to ameliorate the inflammatory reaction to killing bacteria in the lung parenchyma **(CIII)**.

IRIS has not been described in association with bacterial respiratory disease and treatment with ART in HIV-infected persons.

Management of Treatment Failure

Persons who fail to respond to appropriate antimicrobial therapy should undergo further evaluation to search for other infectious and noninfectious causes of pulmonary dysfunction. The possibility of TB should always be considered in HIV-infected persons with pulmonary disease.

Preventing Recurrence

HIV-infected persons should receive pneumococcal and influenza vaccine as recommended. Clinicians can administer antibiotic chemoprophylaxis to HIV-infected patients who have frequent recurrences of serious bacterial respiratory infections **(CIII)**. TMP-SMX, administered for PCP prophylaxis, and clarithromycin or azithromycin, administered for MAC prophylaxis, are appropriate for drug-sensitive organisms. However, health-care providers should be cautious when using antibiotics solely for preventing the recurrence of serious bacterial respiratory infections because of the potential development of drug-resistant microorganisms and drug toxicity.

Special Considerations During Pregnancy

The diagnosis of bacterial respiratory-tract infections among pregnant women is the same as for nonpregnant women, with appropriate shielding of the abdomen during radiographic procedures. Bacterial respiratory-tract infections should be managed as in nonpregnant women, with certain exceptions. Because of an increased risk for birth defects evident in some animal studies, clarithromycin is not recommended as the first-line agent among macrolides. Two studies, each involving at least 100 women with first-trimester exposure to clarithromycin, did not document a clear increase in or specific pattern of birth defects, although an increased risk for spontaneous abortion was noted in one study (*452,453*). Azithromycin did not produce birth defects in animal studies, but experience with human use in the first trimester is limited. Azithromycin is recommended when a macrolide is indicated in pregnancy **(BIII)**. Arthropathy has been noted in immature animals exposed in utero to quinolones. However, approximately 400 cases of quinolone use in human pregnancies have been reported to various pregnancy registries, and use has not been associated with human arthropathy or birth defects after in utero exposure. Thus, quinolones can be used in pregnancy for serious respiratory infections when indicated **(CIII)** (*395*). Doxycycline is not recommended for use during pregnancy because of increased hepatotoxicity and staining of fetal teeth and bones. Beta-lactam antibiotics have not been associated with teratogenicity or increased toxicity in pregnancy. Aminoglycosides may be used as needed. Although a theoretical risk for fetal renal or eighth nerve damage can occur with exposure during pregnancy, this finding has not been documented in humans except with streptomycin (10% risk) and kanamycin (2% risk). Experience with linezolid in human pregnancy has been limited, but it was not teratogenic in mice, rats, and rabbits.

Rates for preterm labor and preterm delivery are increased with pneumonia during pregnancy. Pregnant women with pneumonia after 20 weeks of gestation should be monitored for evidence of contractions **(BII)**.

Pneumococcal vaccine can be administered during pregnancy **(AIII)**. Although its safety during the first trimester of pregnancy has not been evaluated, no adverse consequences have been reported among newborns whose mothers were inadvertently vaccinated during pregnancy. Inactivated influenza vaccine also can be administered during pregnancy, and influenza vaccine is recommended for all pregnant women who will be pregnant during influenza season **(AIII)**. Live attenuated influenza vaccine should not be used during pregnancy **(EIII)**. Because administration of vaccines might be associated with a transient rise in plasma HIV RNA levels, vaccination of pregnant women is recommended after ART has been initiated to minimize increases in plasma HIV RNA levels that might increase the risk for perinatal HIV transmission.

Bacterial Enteric Infections

Epidemiology

Incidence rates of gram-negative bacterial enteric infections are 20- to 100-fold higher among HIV-infected adults than in the general population (*488-492*). The most common causes among adults in the United States are *Salmonella* (particularly *Salmonella* serotypes Typhimurium and Enteritidis), *Shigella*, and *Campylobacter*. As with non-HIV-associated bacterial enteric infections, the probable source for most HIV-infected associated infections is ingestion of contaminated food or water (*490*). Sexual activity with the potential for fecal-oral exposure also increases risk for infections, especially with *Shigella (493*) and *Campylobacter (494*). Acquisition of enteric bacterial infections might be facilitated by HIV-associated gastric achlorhydria, by treatment with agents that decrease gastric acid secretion, and by HIV-associated alterations in mucosal immunity. Although diarrheagenic *Escherichia coli*, especially enteroaggregative *E. coli*, are a frequent cause of diarrhea among HIV-infected persons in resource-limited settings, they do not appear to cause more morbidity in HIV-infected patients than in other persons in more developed regions (*495*).

Clinical Manifestations

The three major clinical syndromes of infection with gram-negative enteric bacteria among HIV-infected patients include the following:

- Self-limited gastroenteritis;
- A more severe and prolonged diarrheal disease, associated with fever, bloody diarrhea, weight loss, and possible bacteremia (bloody diarrhea is more frequent with *Shigella* but also can occur with *Campylobacter* or *Salmonella* (*496,497*); and
- Septicemia, which can exhibit extra-intestinal involvement with or without concurrent or preceding gastrointestinal illness (*498–501*).

The risk for more profound illness increases with the degree of immunosuppression (*488,490,491,502*). Relapses in infections with *Salmonella* and other gram-negative bacterial enteric pathogens after appropriate treatment have been well-documented in HIV-infected patients (*497,503,504*). *Salmonella* is a particularly common cause of septicemia, which is prone to relapse. Recurrent *Salmonella* septicemia constitutes an AIDS-defining illness and might require chronic suppressive therapy (*488*). The development of antimicrobial resistance during therapy, often associated with clinical deterioration

or relapse, can also occur among HIV-infected persons with gram-negative enteridities (*500,501*).

Diagnosis

The diagnosis of gram-negative bacterial enteric infection is established through cultures of stool and blood. Because of the high rate of bacteremia associated with *Salmonella* gastroenteritis in HIV-infected patients, in particular patients with advanced disease, blood cultures should be obtained from any patient with diarrhea and fever.

HIV-infected persons are notably at risk for infection with non-jejuni non-coli *Campylobacter* species, including *C. fetus, C. upsaliensis, C. lari,* and the enterohepatic *Helicobacter* species, *H. cineadi*, and *H. fennelliae* (originally described as *Campylobacter* species). Although blood culture systems will typically grow these bacteria, routine stool cultures performed by most laboratories will fail to identify these more fastidious organisms, which require special conditions for stool culture. Clinicians might wish to notify their clinical laboratory service of a patient's HIV status and to consider evaluation of stool specimens for non-jejuni non-coli *Campylobacter* if initial microbiological evaluation is unrevealing. Endoscopy can be diagnostically useful. If lower endoscopy is performed, ulcerations similar to those seen with CMV colitis might be evident and can only be distinguished through histopathologic examination and culture. Clinicians should notify their microbiology laboratories if they suspect infection with diarrheagenic *E. coli* so that appropriate molecular diagnostic methods can be used or the specimen can be sent to a reference laboratory.

Preventing Exposure

Scrupulous handwashing can reduce risk for diarrhea in HIV-infected persons, including diarrhea caused by enteric bacteria (*242*). HIV-infected persons should be advised to wash their hands after potential contact with human feces (e.g., defecation, cleaning feces from infants), after handling pets or other animals, after gardening or other contact with soil, before preparing food, before eating, and before and after sex **(AIII)**. HIV-infected persons should avoid unprotected sex practices that might result in oral exposure to feces (e.g., anal sex, oral-anal contact) and in addition to hand-washing they should be advised to use barriers during sex to reduce exposures when possible (e.g., condoms, dental dams) **(AIII)**.

Food

Health-care providers should advise HIV-infected persons, particularly those with a $CD4^+$ count <200 cells/μL, not to eat raw or undercooked eggs, including specific foods that might contain raw eggs (e.g., certain preparations of hollandaise sauce, Caesar and other salad dressings, certain mayonnaises (e.g., homemade), uncooked cookie and cake batter, and eggnog); raw or undercooked poultry, meat, and seafood (raw shellfish in particular); unpasteurized dairy products; unpasteurized fruit juices; and raw seed sprouts (e.g., alfalfa sprouts or mung bean sprouts) **(BIII)**. Poultry and meat are safest when adequate cooking is confirmed by thermometer (i.e., internal temperature of 180º F (82º C) for poultry and 165º F (74º C) for red meats). If a thermometer is not used when cooking meats, the risk for illness is decreased by eating poultry and meat that have no trace of pink color. However, color change of the meat (e.g., absence of pink) does not always correlate with internal temperature. Produce should be washed thoroughly before being eaten **(BIII)**.

Health-care providers should advise HIV-infected persons to avoid cross-contamination of foods. Uncooked meats, including hot dogs, and their juices should not come into contact with other foods **(BIII)**. Hands, cutting boards, counters, knives, and other utensils should be washed thoroughly after contact with uncooked foods **(BIII)**.

Health-care providers should advise HIV-infected persons that, although the incidence of listeriosis is low, it is a serious disease that occurs with unusually high frequency among severely immunosuppressed HIV-infected persons. Immunosuppressed, HIV-infected persons who wish to reduce the risk for acquiring listeriosis should adhere to the following precautions **(CIII)**:

- Avoid soft cheeses (e.g., feta, Brie, Camembert, blue-veined, and Mexican-style cheese such as queso fresco); hard cheeses, processed cheeses, cream cheese (including slices and spreads), cottage cheese, or yogurt need not be avoided.
- Cook leftover foods or ready-to-eat foods (e.g., hot dogs) until steaming hot before eating.
- Avoid foods from delicatessen counters (e.g., prepared salads, meats, cheeses) or heat/reheat these foods until steaming before eating.
- Avoid refrigerated pâtés and other meat spreads or heat/reheat these foods until steaming; canned or shelf-stable pâté and meat spreads need not be avoided.
- Avoid raw or unpasteurized milk (including goat's milk) or milk products or foods that contain unpasteurized milk or milk products.

Pets

HIV-infected persons should avoid direct contact with stool from new pets, dogs or cats aged <6 months, or stray pets **(BIII)**. Gloves should always be worn when handling feces or cleaning areas that might have been contaminated by feces from pets **(BIII)**. Persons should avoid or limit contact with reptiles (e.g., snakes, lizards, iguanas, and turtles) and chicks and ducklings because of the risk for salmonellosis **(BIII)**.

Travel

The risk for foodborne and waterborne infections among immunosuppressed, HIV-infected persons is magnified during travel to economically developing countries. Persons who travel to such countries should avoid foods and beverages that might be contaminated, including raw fruits and vegetables, raw or undercooked seafood or meat, tap water, ice made with tap water, unpasteurized milk and dairy products, and items sold by street vendors **(AII)**. Foods and beverages that are usually safe include steaming hot foods, fruits that are peeled by the traveler, bottled (including carbonated) beverages, hot coffee and tea, beer, wine, and water that is brought to a rolling boil for 1 minute. Treating water with iodine or chlorine might not be as effective as boiling and will not prevent infection with *Cryptosporidium* but can be used when boiling is not practical **(BIII)**.

Preventing Disease

Prophylactic antimicrobial agents are not usually recommended for travelers **(DIII)**. The effectiveness of these agents depends on gastrointestinal pathogens' local antimicrobial resistance patterns, which are seldom known. Moreover, these agents can elicit adverse reactions, promote the emergence of resistant organisms, and increase risk for enteric *Clostridium difficile* infection. However, for HIV-infected travelers, antimicrobial prophylaxis can be considered, depending on the level of immunosuppression and the region and duration of travel **(CIII)**. Use of fluoroquinolones or rifaximin can be considered when prophylaxis is deemed necessary **(CIII)**. As an alternative (e.g., for pregnant women and persons already taking TMP-SMX for PCP prophylaxis), TMP-SMX might offer limited protection against traveler's diarrhea **(BIII)**. Risk for toxicity should be considered before treatment with TMP-SMX is initiated solely because of travel.

Treatment of Disease

Immunocompetent hosts without HIV infection often do not require treatment for *Salmonella* gastroenteritis; the condition is self-limited and treatment might prolong the carrier state. However, no treatment trials have examined the strategy of watchful waiting for spontaneous resolution among patients with HIV infection, and the risk for bacteremia is sufficiently high that most specialists recommend treatment of all HIV-associated *Salmonella* infections **(BIII)**.

The initial treatment of choice for *Salmonella* infection is a fluoroquinolone **(AIII)** (*505*). Ciprofloxacin is the preferred agent **(AIII)** (*505*); other fluoroquinolones (levofloxacin and moxifloxacin) also would likely be effective in treatment of salmonellosis among HIV-infected persons, but these agents have not been well-evaluated in clinical studies **(BIII)**. Depending on antibiotic susceptibility, alternatives to the fluoroquinolones might include TMP-SMX or expanded spectrum cephalosporins (e.g., ceftriaxone or cefotaxime) **(BIII)**.

The length of therapy for HIV-related Salmonella infection is poorly defined. For patients with $CD4^+$ counts ≥200 cells/μL and mild gastroenteritis, with or without bacteremia, 7–14 days of treatment for salmonellosis is reasonable **(BIII)**; among patients with advanced HIV disease ($CD4^+$ count <200 cells/μL), a longer course of antibiotics (e.g., 2–6 weeks) is often recommended **(CIII)**.

Therapy for shigellosis is indicated both to shorten the duration of illness and to prevent spread of the infection to others **(AIII)** (*505*). The recommended treatment is with a fluoroquinolone for 3–7 days **(AIII)**. Depending on antibiotic susceptibilities, alternatives to this treatment may include TMP-SMX for 3–7 days or azithromycin for 5 days **(BIII)**. Cases of shigellosis acquired internationally have high rates of TMP-SMX resistance; in addition, HIV-infected persons have higher rates of adverse effects related to this agent. As a result, fluoroquinolones are preferred as first-line treatment. Treating patients who have *Shigella* bacteremia is less well defined. Depending on the severity of infection, extending treatment to 14 days is reasonable, using the agents described previously **(BIII)**.

As with non-HIV-infected patients, the optimal treatment of campylobacteriosis among persons with HIV infection is poorly defined. Among patients with mild disease, some clinicians might opt to withhold therapy unless symptoms persist for more than several days. Increasing resistance to fluoroquinolones makes the choice of therapy especially problematic. For mild-to-moderate campylobacteriosis, initiating therapy with a fluoroquinolone (e.g., ciprofloxacin) or a macrolide (e.g., azithromycin), pending susceptibility test results, and treating for 7 days is a reasonable approach **(BIII)**. Patients with bacteremia should be treated for ≥2 weeks **(BIII)**, and adding a second active agent (e.g., an aminoglycoside) might be prudent **(CIII)**.

Monitoring and Adverse Events, Including Immune Reconstitution Inflammatory Syndrome (IRIS)

Patients should be monitored closely for response to treatment, as defined clinically by improvement in systemic signs and symptoms and resolution of diarrhea. A follow-up stool culture to demonstrate clearance of the organism is not generally required if a complete clinical response has been demonstrated, but should be considered for those patients who fail to respond clinically to appropriate antimicrobial therapy or when public health considerations dictate the need to ensure microbiologic cure (e.g., health-care or food service workers). If after a diagnosis of gram-negative bacterial enteritis and diarrhea

persists or recurs after intervention, other enteric infections should be considered, particularly *Clostridium difficile*.

IRIS has not been described in association with treatment for bacterial enteric diarrhea.

Management of Treatment Failure

Treatment failure is defined by the lack of improvement in clinical signs and symptoms of diarrheal illness and the persistence of organisms in stool, blood, or other relevant body fluids or tissue after completion of appropriate antimicrobial therapy for the recommended duration. Some patients with *Salmonella* bacteremia might remain febrile for 5–7 days despite effective therapy. Therefore, careful observation is required to determine the adequacy of the response.

Treatment should be guided by drug susceptibility testing of isolates recovered in culture. An evaluation of other factors that might contribute to failure or relapse, such as malabsorption of oral antibiotics, a sequestered focus of infection (e.g., an undrained abscess), adverse drug reactions that interfere with antimicrobial activity, or infection with other agents (e.g., *C. difficile*) should be undertaken as indicated.

Preventing Recurrence

HIV-infected persons with *Salmonella* septicemia, which typically occurs in those with advanced HIV disease (e.g., $CD4^+$ count <200 cells/μL), should be monitored clinically for recurrence after treatment **(BIII)**. For persons with recurrent *Salmonella* septicemia, 6 months or more of antibiotics treatment of acute disease should be considered as secondary prophylaxis, although the value of this intervention has not been established and must be weighed against the risks of long-term antibiotic exposure **(CIII)**. In patients who have responded to ART, secondary prophylaxis can probably be stopped. Chronic suppressive or maintenance therapy is not recommended for *Campylobacter* or *Shigella* infections among persons with HIV infection **(EIII)**. Household contacts of HIV-infected persons who have salmonellosis or shigellosis should be evaluated for persistent asymptomatic carriage of *Salmonella* or *Shigella* so that strict hygienic measures or antimicrobial therapy can be instituted and recurrent transmission to the HIV-infected person prevented **(BIII)**.

Special Considerations During Pregnancy

The diagnosis of bacterial enteric infections among pregnant women is the same as among nonpregnant women. Bacterial enteric infections in the pregnant woman should be managed as in the nonpregnant woman, with several considerations. Arthropathy has been noted in immature animals when quinolones are used during pregnancy. However, approximately 400 cases of quinolone use in pregnancy have been reported to various pregnancy registries, and use has not been associated with arthropathy or birth defects after in utero exposure. Thus, quinolones can be used in pregnancy for bacterial enteric infections in HIV-infected pregnant women as indicated **(CIII)** (*395*). Alternate agents for use in pregnancy include expanded spectrum cephalosporins, TMP-SMX, or azithromycin, depending on the organism and the results of susceptibility testing **(CIII)**. Neonatal-care providers should be informed if maternal sulfa therapy is used near delivery because of the theoretical increased risk for hyperbilirubinemia and kernicterus to the newborn.

Bartonellosis

Epidemiology

Bartonella species cause infections that include cat scratch disease, trench fever, relapsing bacteremia, endocarditis, bacillary angiomatosis (BA), and bacillary peliosis hepatis (*506*). The latter two manifestations occur only in immunocompromised persons. BA is caused by either *B. quintana* or *B. henselae* (*506,507*). Nineteen species of *Bartonella* have been identified, and five have been isolated from humans. However, only *B. henselae* and *B. quintana* infections have been identified in HIV-infected persons (*507*). BA most often occurs late in HIV infection, in patients with a median $CD4^+$ count of <50 cells/μL (*507*). In HIV-infected patients, bartonellosis is often a chronic illness, lasting for months to years, with BA lesions and intermittent bacteremia.

Development of BA lesions caused by *B. henselae* is statistically linked to cat exposure in patients with HIV infection (*507*). In contrast, BA caused by *B. quintana* is associated with body louse infestation and homelessness (*507*). The body louse serves as the vector of *B. quintana* among humans. The cat flea is the vector of *B. henselae* among cats. However, the cat is the most common vector (via a scratch) that is responsible for transmitting *B. henselae* to humans, most likely when claws become contaminated with feces from *B. henselae*-infected fleas. In some areas of the United States, the prevalence of *B. henselae* bacteremia in pet cats approaches 50% (*508*). Control of cat flea infestation and avoidance of cat scratches are therefore critical strategies for prevention of *B. henselae* infections in HIV-infected persons. To avoid exposure to *B. quintana*, HIV-infected patients should avoid and treat infestation with body lice.

Clinical Manifestations

BA lesions have been associated with nearly every organ system, but cutaneous lesions are the most readily identified. BA lesions can be clinically indistinguishable from KS. BA also can cause subcutaneous nodules. Osteomyelitis is usually caused by *B. quintana*, and only *B. henselae* can cause bacillary peliosis

hepatis. Although isolated organs can appear to be the principal focus of disease, BA represents a hematogenously disseminated infection, and systemic symptoms of fever, night sweats, and weight loss often accompany BA. *Bartonella* infection is a major cause of unexplained fever in late-stage AIDS patients and should be considered in the differential diagnosis of patients with fever and a $CD4^+$ count of <100 cells/μL (*509*).

Diagnosis

Diagnosis can be confirmed by histopathologic examination of biopsied tissue (*510*). BA lesions are characterized by vascular proliferation, and a modified silver stain (e.g., Warthin-Starry stain) usually demonstrates numerous bacilli. Tissue Gram staining and acid-fast staining are negative.

A well-characterized serologic test was developed at CDC (*511*) and is also available at some state health labs. In addition, several private laboratories offer serological testing, but none of these private laboratory tests has been evaluated for sensitivity or specificity with sera from HIV-infected patients. In immunocompetent patients, anti-*Bartonella* antibodies might not be detectable for 6 weeks after acute infection; in contrast, by the time *Bartonella* infection is suspected in patients with late-stage HIV infection, they usually have been infected for months or even >1 year. Note that as many as 25% of *Bartonella* culture-positive patients might never develop antibodies in the setting of advanced HIV infection (*509*). In those patients who do develop anti-*Bartonella* antibodies, monitoring of antibody levels might correlate with resolution and recrudescence of *Bartonella* infection.

Bartonella species can be isolated (with difficulty) from blood, using EDTA tubes. The organisms have been isolated from tissue in only a few laboratories because of the fastidious nature of *Bartonella (507*). PCR methods have been developed for identification and speciation of *Bartonella,* but are not widely available.

Preventing Exposure

HIV-infected persons, specifically those who are severely immunocompromised ($CD4^+$ counts <100 cells/μL), are at high risk for severe disease caused by *B. quintana* and *B. henselae*. The major risk factors for acquisition of *B. henselae* are contact with cats infested with fleas and receiving cat scratches. Immunocompromised persons should consider the potential risks of cat ownership **(AIII)**. Persons who acquire a cat should acquire an animal aged >1 year and in good health **(BII)**. Cats should be acquired from a known environment, have a documented health history, and be free of fleas. Stray cats and cats with flea infestation should be avoided. Declawing is not advised, but HIV-infected persons should avoid rough play with cats and situations in which scratches are likely **(AII)**. Patients should avoid contact with flea feces ("flea dirt"), and any cat-associated wound should be washed promptly **(BIII)**. Care of cats should include a comprehensive, ongoing flea-control program under the supervision of a veterinarian **(BIII)**. No evidence indicates any benefits to cats or their owners from routine culture or serologic testing of the pet for *Bartonella* infection or from antibiotic treatment of healthy, serologically positive cats **(DII)**. The major risk factor for *B. quintana* infection is body lice infestation. Homeless or marginally housed persons should be informed that body louse infestation can be associated with serious illness and provided with appropriate measures to eradicate body lice, if present **(AII)**.

Preventing Disease

Primary chemoprophylaxis for *Bartonella*-associated disease is not recommended **(DIII)**. However, note that in a retrospective case-control study, MAC prophylaxis using a macrolide or rifamycin was protective against developing *Bartonella* infection (*507*).

Treatment of Disease

Guidelines for treatment of Bartonella infections have been published (*512*). No randomized, controlled clinical trials have evaluated antimicrobial treatment of bartonellosis in HIV-infected patients. Erythromycin and doxycycline have been used successfully to treat BA, peliosis hepatis, bacteremia, and osteomyelitis and are considered first-line treatment for bartonellosis, on the basis of reported experience in case series **(AII)** (*506*,*507*). Therapy should be administered for ≥3 months **(AII)**. Doxycycline, with or without RIF, is the treatment of choice for bartonellosis infection involving the central nervous system (CNS) and other severe bartonellosis infections **(AIII)**.

Clarithromycin or azithromycin treatment has been associated with clinical response and either of these can be an alternative for *Bartonella* treatment **(BIII)**. Azithromycin is recommended for patients who are less likely to comply with the more frequent dosing schedule for doxycycline or erythromycin. Penicillins and first-generation cephalosporins have no in vivo activity and should not be used for treatment of bartonellosis **(DII)**. Quinolones and TMP-SMX have variable in vitro activity and an inconsistent clinical response in case reports and are not recommended **(DIII)**.

IRIS has not been described in association with *Bartonella* infection, but patients with *Bartonella* CNS or ophthalmic lesions should probably be treated with doxycycline and RIF for 2–4 weeks before instituting ART.

Monitoring and Adverse Effects, Including Immune Reconstitution Inflammatory Syndrome (IRIS)

Patients treated with oral doxycycline should be cautioned about pill-associated ulcerative esophagitis that occurs most often when a dose is taken with only a small amount of liquid or at night just before retiring **(AIII)** (*513*).

No immune inflammatory response syndrome has been described in association with Bartonellosis and treatment with ART in HIV-infected persons.

Management of Treatment Failure

Among patients who fail to respond to initial treatment, one or more of the second-line alternative regimens should be considered **(AIII)**.

Preventing Recurrence

Relapse can occur after a course of primary treatment. In this setting, long-term suppression of infection with doxycycline or a macrolide is recommended, as long as the $CD4^+$ count remains <200 cells/μL **(AIII)**.

Long-term suppression can be discontinued after the patient has received 3–4 months of therapy and when the $CD4^+$ count remains >200 cells/μL for ≥6 months **(CIII)**. Certain specialists would discontinue therapy only if the *Bartonella* titers have also decreased by fourfold **(CIII)**.

Special Considerations During Pregnancy

Infection with *B. bacilliformis* in immunocompetent patients during pregnancy has been associated with increased complications and risk for death (*514*). No data are available on the effect of *B. henselae* or *B. quintana* infections in pregnant women with concomitant HIV infection.

The approach to diagnosis of *Bartonella* infections in pregnant women is the same as in nonpregnant women. Erythromycin treatment should be used **(AIII)** rather than tetracyclines **(EII)** during pregnancy because of the increased risk for hepatotoxicity and the accumulation of tetracycline in fetal teeth and bones, resulting in dark, permanent staining of fetal teeth. Third-generation cephalosporins (e.g., ceftizoxime (*515*) or ceftriaxone) might have efficacy against *Bartonella* in the pregnant HIV-infected woman, but should be considered second-line therapy after a macrolide. First- and second-generation cephalosporins are not recommended because of their lack of efficacy against *Bartonella* **(EII)**.

Syphilis

Epidemiology

Syphilis is associated with increased risk for HIV sexual acquisition and transmission (*516,517*). Recent reports indicate a resurgence of syphilis among men in several U.S. cities and in Western Europe (*518–524*). Although coexistent HIV infection, particularly in the advanced stages, can modify the diagnosis, natural history, or management of *Treponema pallidum* infection, the principles of syphilis management are the same for persons with and without coexistent HIV infection (*525–529*). Recent syphilis treatment recommendations are available in the 2006 CDC STD Treatment Guidelines (*529,530*).

Clinical Manifestations

Despite multiple case reports and small case series, limited large studies have documented the effect of coexistent HIV on the protean manifestations of syphilis. The few larger studies suggest that HIV infection might shift the clinical manifestations of syphilis, making clinical lesions more apparent, and might accelerate progression of syphilitic disease (*526,527*). Early syphilis in HIV-infected persons may also cause a transient decrease in $CD4^+$ count and increase in HIV viral load that improves with standard treatment regimens (*531–533*).

Primary syphilis commonly exhibits a single painless nodule at the site of contact that rapidly ulcerates to form a classic chancre; however, among HIV-infected persons, multiple or atypical chancres occur and primary lesions might be absent or missed (*526,534*).

Progression to secondary syphilis typically follows 2–8 weeks after primary inoculation. Although more rapid progression or severe disease might occur among HIV-infected persons with advanced immunosuppression, the clinical manifestations are similar to those among HIV-uninfected persons. The manifestations of secondary syphilis involve virtually all organ systems. The most common manifestations, macular, maculopapular, papulosquamous, or pustular skin lesions, usually begin on the trunk and spread peripherally, involving palms and soles and accompanied by generalized lymphadenopathy and fever, malaise, anorexia, arthralgias, and headache (*527–529*). Condyloma lata, moist, flat, papular lesions in warm intertrigenous regions, might resemble papilloma virus infection. Secondary syphilis, particularly acute syphilitic meningitis, can resemble acute primary HIV infection; constitutional symptoms, along with nonfocal CNS symptoms and CSF abnormalities (e.g., lymphocytic pleocytosis with a mildly elevated CSF protein), are common to both (*534–539*).

Signs and symptoms of secondary syphilis can persist from a few days to several weeks before resolving and evolving to latent or later stages. Latent syphilis lacks overt clinical signs and symptoms, but relapse of manifestations of secondary syphilis might occur, most commonly during the first 1–4 years following infection.

Manifestations of "late" syphilis generally include neurosyphilis, cardiovascular syphilis, and gummatous syphilis or

a slowly progressive disease that can affect any organ system. Neurosyphilis can occur at any stage of syphilis. Asymptomatic neurosyphilis is defined as one or more CSF abnormalities (i.e., elevated protein, lymphocytic pleocytosis, or positive VDRL) in the absence of symptoms or signs. Manifestations of symptomatic neurosyphilis (i.e., meningitis or meningovascular or parenchymatous disease) among HIV-infected persons are similar to those in the HIV-uninfected persons. However, clinical manifestations of neurosyphilis, such as concomitant uveitis and meningitis, might be more common among HIV-infected persons (*538*).

Diagnosis

The diagnosis of syphilis depends on direct detection of the organism (e.g., by darkfield microscopy, direct fluorescent antibody-*Treponema pallidum*, biopsy with silver stain), or on presumptive serologic diagnosis based upon nontrepomenal tests (e.g., Venereal Disease Research Laboratory [VDRL] and rapid plasma reagin [RPR]) and treponemal tests (e.g., FTA-ABS and TP-PA). The serologic diagnosis of syphilis traditionally has involved screening for nontreponemal antibodies with confirmation of reactive tests by treponemal-based assays (*529,540*). Recently, some laboratories have initiated a testing algorithm using treponemal-based enzyme immunoassay (EIA) as a screening test with nontreponemal testing for confirmation. This latter strategy may more often identify those with a previous syphilis infection along with those having untreated infection (*541*). Clinical experience suggests that concurrent HIV infection probably does not change the performance of standard tests for the diagnosis of syphilis. However, false-positive nontreponemal serologic tests that are not confirmed by treponemal serologic tests might be more common among HIV-infected persons (*542,543*).

Early-stage disease (i.e., primary, secondary, and early-latent syphilis) among HIV-infected persons is confirmed by the identical procedures used for the HIV-uninfected person (e.g., darkfield microscopy of a mucocutaneous lesion and standard serologic tests). HIV infection does not decrease the sensitivity or specificity of darkfield microscopy. Responses to nontreponemal serologic tests (i.e., VDRL and RPR) might be atypical (i.e., higher, lower, or delayed) among HIV-infected versus HIV-uninfected persons with early-stage syphilis (*543,544*). No data indicate that treponemal tests perform differently among HIV-infected compared with -uninfected patients (*545*). Similar to HIV-uninfected persons, false-negative serologic tests for syphilis can occur both among HIV-uninfected and HIV-infected persons with documented *T. pallidum* infection (*546,547*). Therefore, if serologic tests do not confirm the diagnosis of suspected syphilis, other diagnostic procedures (e.g., repeat serology in 1–2 weeks, exclusion of prozone phenomenon, biopsy, darkfield examination, or direct fluorescent antibody staining of lesion material) should be pursued. By definition, persons with latent syphilis have serological evidence of syphilis in the absence of clinical or other laboratory abnormalities (i.e., normal CSF profiles). Patients with early-latent syphilis have documented infection of <1 year; persons with late-latent syphilis have documented infection for >1 year or the duration of infection is not known. The diagnostic testing recommended for detection of late-stage syphilis (e.g., cardiovascular and gummatous syphilis) among HIV-infected persons is the same as for the HIV-uninfected person.

All persons with syphilis, regardless of disease stage, should be evaluated for clinical evidence of CNS or ocular involvement. CSF abnormalities (elevated protein and mononuclear pleocytosis) are common in early syphilis and in persons with HIV infection. However, whether the prognostic significance of such CSF abnormalities differs between HIV-infected persons and HIV-uninfected persons with primary, secondary, or early-latent syphilis is unknown.

CSF examination should be performed in persons with neurologic or ocular signs or symptoms, active tertiary syphilis, and treatment failure. CSF examination is also recommended for HIV-infected persons with late-latent syphilis, including those with syphilis of unknown duration. Some specialists recommend CSF examination for all HIV-infected persons with syphilis regardless of stage, particularly if serum RPR is 1:32 or with a $CD4^+$ count of <350 cells/μL *(537,539)*. The risk for developing clinical neurosyphilis in this circumstance is unknown. CSF abnormalities consistent with neurosyphilis should be treated using standard neurosyphilis treatment regimens.

Among persons without HIV infection, diagnosis of neurosyphilis is established by CSF examination, which might indicate mild mononuclear pleocytosis (e.g., 10–200 cells/μL), normal or mildly elevated protein concentration, or a reactive CSF-VDRL (*529,537,539*). The CSF-VDRL is specific but not sensitive, and a reactive test establishes the diagnosis of neurosyphilis, but a nonreactive test does not exclude the diagnosis. In comparison, CSF treponemal tests (e.g., the CSF FTA-ABS) are sensitive but not specific, with a nonreactive test excluding the diagnosis of neurosyphilis. Calculated indices (e.g., TPHA-index) are of limited value in establishing the diagnosis of neurosyphilis. PCR-based diagnostic methods are not currently recommended as a diagnostic test for neurosyphilis. A reactive CSF-VDRL and a CSF WBC >10 cells/μL support the diagnosis of neurosyphilis; the majority of specialists would not base the diagnosis solely on elevated CSF protein concentrations in the absence of these other abnormalities.

Establishing the diagnosis of neurosyphilis can be more difficult among persons with HIV infection, because HIV infection itself might be associated with mild mononuclear CSF pleocytosis (5–15 cells/μL), particularly among persons with peripheral blood CD4$^+$ counts >500 cells/μL. If neurosyphilis cannot be excluded by a nonreactive CSF treponemal test, such persons should be treated for neurosyphilis, despite the acknowledged uncertainty of the diagnosis.

Preventing Exposure

The resurgence of syphilis among persons with HIV infection in the United States underscores the importance of primary prevention of syphilis among persons with HIV infection. This should begin with routine discussion of sexual behaviors. Providers should discuss client-centered risk reduction messages and provide specific actions that can reduce the risk for acquiring sexually transmitted infections and for transmitting HIV (*529,548–550*). Routine serologic screening for syphilis is recommended at least annually for all sexually active HIV-infected persons, with more frequent screening (every 3–6 months) for those with multiple partners, unprotected intercourse, sex in conjunction with illicit drug use, methamphetamine use, or partners who participate in such activities (*529,551*). The occurrence of syphilis in an HIV-infected person is an indication of high-risk behavior and should prompt intensified counseling messages and strong consideration of referral for behavioral intervention. Persons undergoing screening or treatment for syphilis also should be evaluated for all common sexually transmitted diseases (STDs) (*529*).

Preventing Disease

The same measures that apply to preventing exposure apply to preventing disease.

Treatment of Disease

Management of syphilis in HIV-infected persons is similar to the management in HIV-uninfected persons (*529,530,544*). However, closer follow-up is recommended to detect potential treatment failure or disease progression.

Penicillin remains the treatment of choice for syphilis regardless of HIV status. HIV-infected persons with early-stage (i.e., primary, secondary, or early-latent) syphilis should receive a single intramuscular (IM) injection of 2.4 million units of benzathine penicillin G **(AII)**. Although most HIV-infected persons with early syphilis respond appropriately to standard benzathine penicillin, some specialists recommend two additional weekly benzathine penicillin injections. The benefit of this treatment approach remains unproven. Enhanced penicillin therapy (i.e., standard benzathine penicillin with high-dose oral amoxicillin and probenecid) did not improve clinical outcome in early-stage syphilis (*544*) and is not recommended **(DII)** .

The efficacy of alternative nonpenicillin regimens in HIV-infected persons with early syphilis, including oral doxycycline, ceftriaxone, and azithromycin, has not been evaluated sufficiently in HIV-infected persons to warrant use as first-line treatment. Regardless of HIV infection status, the use of any alternative penicillin treatment regimen should be undertaken only with close clinical and serologic monitoring **(BIII)**. Similarly, although some evidence suggests that a single 2-gram oral dose of azithromycin might have efficacy for treating early syphilis (*552,553*), molecular resistance of *T. pallidum* to macrolides and clinical treatment failures with azithromycin have been reported (*554–556*); such treatment should be used only with close clinical and serologic monitoring to detect treatment failure **(CII)**.

In HIV-infected persons with late-latent syphilis for whom the CSF examination excludes the diagnosis of neurosyphilis, treatment with three weekly IM injections of 2.4 million units benzathine penicillin G is recommended **(AIII)**. Alternative therapy with doxycycline 100 mg by mouth twice a day for 28 days has not been sufficiently evaluated in HIV-infected persons to warrant use as first-line treatment **(BIII)**. If the clinical situation requires the use of an alternative to penicillin, treatment should be undertaken with close clinical and serologic monitoring.

HIV-infected persons with clinical evidence of late-stage (tertiary) syphilis (cardiovascular or gummatous disease) should have a CSF examination to rule out neurosyphilis before initiating therapy. The complexity of tertiary syphilis management is beyond the scope of these guidelines and providers are advised to consult an infectious disease specialist.

HIV-infected persons with clinical or laboratory evidence of neurosyphilis (i.e., CNS, otic, or ocular disease) should receive IV aqueous crystalline penicillin G, 18–24 million units daily, administered 3–4 million units IV every 4 hours or by continuous infusion for 10–14 days **(AII)** or procaine penicillin 2.4 million units IM once daily plus probenecid 500 mg orally four times a day for 10–14 days **(BII)** (*529,537,539*). HIV-infected persons who are allergic to sulfa-containing medications should not be administered probenecid because of potential allergic reaction **(DIII)**.

Because neurosyphilis treatment regimens are of shorter duration than those used in late-latent syphilis, some specialists recommend 2.4 million units IM once per week for up to 3 weeks after completion of neurosyphilis treatment to provide a comparable duration of therapy **(CIII)** (*529*). Among patients who are allergic to penicillin, penicillin desensitization is the preferred approach to treating neurosyphilis **(BIII)**. However, limited data indicate that ceftriaxone (2 g daily IV for 10–14

days) might be an acceptable alternative regimen **(CIII)** (*557*). Other alternative regimens for neurosyphilis have not been evaluated adequately.

Monitoring and Adverse Events, Including Immune Reconstitution Inflammatory Syndrome (IRIS)

Clinical and serologic responses to treatment of early-stage (i.e., primary, secondary, and early-latent) disease should be monitored at 3, 6, 9, 12, and 24 months after therapy. Serologic responses to treatment are similar in persons with and without HIV infection; however, subtle variations might occur, including the temporal pattern of response (*529,530,544,558*).

After successful treatment for syphilis (HIV-infected and -uninfected persons), 15%–20% of persons might remain "serofast," meaning that serum nontreponemal test titers remain reactive at low and unchanging titers, usually <1:8, for prolonged periods *(529,544)*. This serofast state probably does not represent treatment failure. Serologic detection of potential reinfection should be based on an at least a fourfold increase in titer above the established serofast baseline.

Response to therapy of late-latent syphilis should be monitored using nontreponemal serologic tests at 6, 12, 18, and 24 months to ensure at least a fourfold decline in titer. Some retrospective studies have documented concomitant HIV infection associated with poorer CSF and serologic responses to neurosyphilis therapy (*559,560*). CSF examination should be repeated at 6 months after completion of therapy. If clinical symptoms develop or nontreponemal titers rise fourfold, a repeat CSF examination should be performed and treatment administered accordingly. The earliest CSF indicator of response to neurosyphilis treatment is a decline in CSF lymphocytosis. The CSF VDRL might respond more slowly. Nontreponemal serum titers should be monitored during the next 12–24 months and if the titers do not decline fourfold, consultation with an infectious disease specialist is recommended (*529*).

No IRIS has been described in association with syphilis and treatment with ART in HIV-infected persons.

Management of Treatment Failure

Retreatment of persons with early-stage syphilis should be considered for those who 1) have a sustained fourfold increase in serum nontreponemal titers after an initial reduction after treatment, or 2) have persistent or recurring clinical signs or symptoms of disease **(BIII)**. Certain specialists recommend retreating persons with early syphilis who do not experience at least a fourfold decrease in serum nontreponemal titers 6–12 months after therapy **(BIII)**. If CSF examination does not confirm the diagnosis of neurosyphilis, such persons should receive 2.4 million units IM benzathine penicillin G administered at 1-week intervals for 3 weeks **(BIII)**. Certain specialists also recommend a course of aqueous penicillin G administered IV or procaine penicillin administered IM plus probenecid for treatment of neurosyphilis in this setting, although data to support this practice are lacking **(CIII)**. If titers do not respond appropriately after retreatment, the value of repeated CSF examination or additional therapy has not been established. Persons with HIV infection might be at increased risk for treatment failure and neurologic complications; the magnitude of these risks is not precisely defined but is likely low (*536,561*).

Persons with late-latent syphilis should have a repeat CSF examination and be retreated if they have clinical signs or symptoms of syphilis, have a fourfold increase in serum nontreponemal test titer, or experience an inadequate serologic response (less than four-fold decline in nontreponemal test titer) within 12–24 months of therapy **(BIII)**. If the CSF examination is consistent with CNS involvement, retreatment should follow the neurosyphilis recommendations **(AIII)**. Persons with latent syphilis and a normal CSF examination should be treated with benzathine penicillin, 2.4 million units IM weekly for 3 weeks **(BIII)**; certain specialists also recommend adding a neurosyphilis regimen in this setting **(CIII)**. Retreatment for neurosyphilis should then be considered if the CSF WBC count has not decreased 6 months after completion of treatment or if the CSF-VDRL remains reactive 2 years after treatment **(BIII)**.

Preventing Recurrence

No recommendations indicate the need for secondary prophylaxis or prolonged chronic maintenance antimicrobial therapy for syphilis in HIV-infected persons. Targeted mass treatment of high-risk populations has not been demonstrated to be effective and is not recommended. Azithromycin is not recommended as secondary prevention because of azithromycin treatment failures reported in HIV-infected persons and reports of macrolide-resistant *T. pallidum (554–556)*.

Special Considerations During Pregnancy

Pregnant women should be screened for syphilis at the first prenatal visit. In areas where syphilis prevalence is high or among women at high risk (e.g., uninsured, women living in poverty, commercial sex workers, and IDUs), testing should be repeated at 28–32 weeks of gestation and at delivery. All women delivering a stillborn infant after 20 weeks of gestation also should be tested for syphilis. Syphilis screening should also be offered at sites providing episodic care to pregnant women at high risk, including emergency departments, jails, and prisons. No infant should leave the hospital without documentation of maternal syphilis-serology status during pregnancy (*562*).

The rate of transmission to the fetus and adverse pregnancy outcomes of untreated syphilis are highest with primary, secondary, and early-latent syphilis during pregnancy and decrease with increasing duration of infection thereafter. Pregnancy does not appear to alter the clinical course, manifestations, or diagnostic test results of syphilis infection among adults. Concurrent syphilis infection has been associated with increased risk for perinatal transmission of HIV to the infant (*563–568*).

Treatment during pregnancy should consist of the same penicillin regimen as recommended for the given disease stage among nonpregnant, HIV-infected adults. Because of treatment failures reported after single injections of benzathine penicillin G among HIV-uninfected pregnant women (*569*), certain specialists recommend a second injection 1 week after the initial injection for pregnant women with early syphilis (*529,570*). Because of additional concerns about the efficacy of standard therapy in HIV-infected persons, a second injection in 1 week for HIV-infected pregnant women should be considered **(BIII)**.

No alternatives to penicillin have been proven effective and safe for treatment of syphilis during pregnancy or for prevention of fetal infection. Pregnant women who have a history of penicillin allergy should be referred for skin testing and desensitization and treatment with penicillin **(AIII)** (*529*). Erythromycin does not reliably cure fetal infection; tetracyclines should not be used during pregnancy because of hepatotoxicity and staining of fetal bones and teeth **(EIII)**. However, because of insufficient information regarding the use of azithromycin (*571*) or ceftriaxone (*572*) treatment in pregnancy, routine use is not a recommended **(DIII)**.

A Jarisch-Herxheimer reaction that occurs during the second half of pregnancy might precipitate preterm labor or fetal distress (*573*). Women should be advised to seek obstetric attention after treatment if they notice contractions or a decrease in fetal movement during the first 24 hours after treatment. During the second half of pregnancy, syphilis management may be facilitated by a sonographic fetal evaluation for congenital syphilis, but this evaluation should not delay therapy. Sonographic signs of fetal or placental syphilis indicate a greater risk for fetal treatment failure. Such cases should be managed in consultation with obstetric specialists. Evidence is insufficient to recommend specific regimens for these situations. After >20 weeks of gestation, fetal and contraction monitoring for 24 hours after initiation of treatment for early syphilis should be considered when sonographic findings indicate fetal infection.

Repeat serologic titers should be performed in the third trimester and at delivery for women treated for syphilis during pregnancy. Data related to serologic response to syphilis in HIV-infected women are insufficient. Titers can be conducted monthly for women at high risk for reinfection. Clinical and antibody response should be appropriate for the stage of disease, although the majority of women will deliver before their serologic response can be definitively assessed. Maternal treatment is likely to be inadequate if delivery occurs within 30 days of therapy, if clinical signs of infection are present at delivery or if the maternal antibody titer is fourfold higher than the pretreatment titer.

Mucocutaneous Candidiasis

Epidemiology

Oropharyngeal and esophageal candidiasis are common (*574*). The majority of infection is caused by *Candida albicans*. Fluconazole (or azole) resistance is predominantly the consequence of previous exposure to fluconazole (or other azoles), particularly repeated and long-term exposure (*575–577*). In this setting, *C. albicans* resistance has been accompanied by a gradual emergence of non-*albicans Candida* species, particularly *C. glabrata*, as a cause of refractory mucosal candidiasis, particularly in patients with advanced immunosuppression (*575,578*).

The occurrence of oropharyngeal or esophageal candidiasis is recognized as an indicator of immune suppression, and these are most often observed in patients with $CD4^+$ counts <200 cells/μL (*574*). In contrast, vulvovaginal candidiasis is common among healthy, adult women and is unrelated to HIV status. Recurrent vulvovaginal candidiasis alone should not be considered a sentinel of HIV infection among women. The introduction of ART has led to a dramatic decline in the prevalence of oropharyngeal and esophageal candidiasis and a marked diminution in cases of refractory disease.

Clinical Manifestations

Oropharyngeal candidiasis is characterized by painless, creamy white, plaque-like lesions of the buccal or oropharyngeal mucosa or tongue surface. Lesions can be easily scraped off with a tongue depressor or other instrument. Less commonly, erythematous patches without white plaques can be seen on the anterior or posterior upper palate or diffusely on the tongue. Angular chelosis is also noted on occasion and might be caused by *Candida*.

Esophageal candidiasis is occasionally asymptomatic but retrosternal burning pain or discomfort and odynophagia are often present. Endoscopic examination reveals whitish plaques similar to those observed with oropharyngeal disease that might progress to superficial ulceration of the esophageal mucosa, with central or surface whitish exudates.

Candida vulvovaginitis might be mild to moderate and sporadic, similar to that in normal hosts, and be characterized by a

white adherent vaginal discharge associated with mucosal burning and itching. In those with advanced immunosuppression, episodes might be more severe and more frequently recurrent. Compared with oropharyngeal candidiasis, vaginal candidiasis is less frequent and rarely refractory to azole therapy.

Diagnosis

Diagnosis of oropharyngeal candidiasis is usually clinical and based on the appearance of lesions. The feature that distinguishes these from oral hairy leukoplakia is the ability to scrape off the superficial whitish plaques. If laboratory confirmation is required, a scraping for microscopic examination for yeast forms using a potassium hydroxide (KOH) preparation provides supportive diagnostic information. Cultures of clinical material identify the species of yeast present.

The diagnosis of esophageal candidiasis requires endoscopic visualization of lesions with histopathologic demonstration of characteristic *Candida* yeast forms in tissue and culture confirmation of the presence of *Candida* species. The diagnosis of vulvovaginal candidiasis is based on the clinical presentation coupled with the demonstration of characteristic pseudohyphal yeast forms in vaginal secretions examined microscopically after KOH preparation. Culture confirmation is rarely required but might provide supportive information. Because self-diagnosis of vulvovaginitis is unreliable, microscopic and culture confirmation is required to avoid unnecessary exposure to inappropriate treatments.

Preventing Exposure

Candida organisms are common commensals on mucosal surfaces in healthy persons. No measures are available to reduce exposure to these fungi.

Preventing Disease

Data from prospective controlled trials indicate that fluconazole can reduce the risk for mucosal (e.g., oropharyngeal, esophageal, and vaginal) candidiasis among patients with advanced HIV disease (*579–582*). However, routine primary prophylaxis is not recommended because mucosal disease is associated with very low attributable mortality, acute therapy is highly effective, prophylaxis can lead to disease caused by drug-resistant species, prophylactic agents can produce drug interactions, and prophylaxis is expensive (**DIII**). ART does reduce the likelihood of mucosal candidiasis **(AI)**.

Treatment of Disease

Oral fluconazole is as effective and, in certain studies, superior to topical therapy for oropharyngeal candidiasis. In addition, it is more convenient and typically better tolerated. Therefore, oral fluconazole is considered the drug of choice **(AI)** (*583*).

Initial episodes of oropharyngeal candidiasis can be adequately treated with topical therapy, including clotrimazole troches, nystatin suspension or pastilles, or once-daily miconazole mucoadhesive tablets **(BII)** (*584*).

Itraconazole oral solution for 7–14 days is as effective as oral fluconazole but less well tolerated **(AI)**. Posaconazole oral solution (*585*) is also as effective as fluconazole and is generally better tolerated than itraconazole **(AI).** They are alternatives to oral fluconazole, although few situations require that these drugs would be used in preference to fluconazole solely to treat mucosal candidiasis. In a multicenter, randomized study, posaconazole was proven more effective than fluconazole in sustaining clinical success after antifungal therapy was discontinued (*585*). Ketoconazole and itraconazole capsules are less effective than fluconazole because of their more variable absorption. Using these agents to treat mucosal candidiasis is not reasonable if the other options are available **(DIII)**.

Systemic antifungals are required for effective treatment of esophageal candidiasis **(AI)**. A 14–21-day course of either fluconazole (oral or IV) or oral itraconazole solution is highly effective **(AI)**. As with oropharyngeal candidiasis, oral ketoconazole or itraconazole capsules are less effective than fluconazole because of variable absorption **(DII)**. Although IV caspofungin **(BI)** or IV voriconazole **(BI)** are effective in treating esophageal candidiasis among HIV-infected patients, oral or IV fluconazole remain the preferred therapies **(AI)**.

Two additional parenteral echinocandins, micafungin and anidulafungin, also are approved for the treatment of esophageal candidiasis. Although the three echinocandins are as effective as fluconazole in the treatment of esophageal candidiasis, they all appear to have a greater relapse rate when compared with fluconazole (*586,587*). Although symptoms of esophageal candidiasis might be mimicked by other pathogens, a diagnostic trial of antifungal therapy is usually appropriate before endoscopy is used to identify causes of esophagitis **(CII)**.

Vulvovaginal candidiasis in HIV-infected women is usually uncomplicated (90%) and responds readily to short-course oral or topical treatment with any of several therapies, including the following regimens:

- Oral fluconazole **(AII)**
- Topical azoles (clotrimazole, butaconazole, miconazole, ticonazole, or terconazole **(AII)**
- Itraconazole oral solution **(BII)**

Severe or recurrent episodes of vaginitis require oral fluconazole or topical antifungal therapy for ≥7 days **(AIII)**.

ART reduces the frequency of mucosal candidiasis. Refractory cases of mucosal candidiasis typically resolve when immunity improves in response to ART.

IRIS has not been reported in association with episodes of mucosal candidiasis in HIV-positive persons.

Monitoring and Adverse Events, Including Immune Reconstitution Inflammatory Syndrome (IRIS)

For the majority of patients with mucocutaneous candidiasis, response to therapy is rapid, with improvement in signs and symptoms within 48–72 hours. Short courses of topical therapy rarely result in adverse effects, although patients might experience cutaneous hypersensitivity reactions, characterized rash, and pruritus. Oral azole therapy can be associated with nausea, vomiting, diarrhea, abdominal pain, or transaminase elevations. If prolonged azole therapy is anticipated (>21 days), periodic monitoring of liver chemistry studies should be considered **(CIII)**.

The echinocandins thus far appear to be safe and free of substantial side effects; histamine-related infusion toxicity, elevation of transaminase, and rash have been attributed to these drugs. No dose adjustments are required in renal failure.

IRIS has not been described because of *Candida*.

Management of Treatment Failure or Refractory Mucosal Candidiasis

Refractory oral or esophageal candidiasis is still reported in approximately 4%–5% of HIV-infected persons, typically in those patients with $CD4^+$ counts <50 cells/μL who have received multiple courses of azole antifungals.

Treatment failure is typically defined as signs and symptoms of oropharyngeal or esophageal candidiasis that persist after more than 7–14 days of appropriate therapy. Oral itraconazole solution is effective at least transiently in approximately two thirds of persons with fluconazole-refractory mucosal candidiasis **(AII).** Posaconazole immediate-release oral suspension (400 mg bid for 28 days) is effective in 75% of patients with azole refractory oropharyngeal and/or esophageal candidiasis **(AII)** (*588*).

IV amphotericin B is usually effective and can be used among patients with refractory disease **(BII)**. Both conventional amphotericin B and lipid complex and liposomal amphotericin B have been used **(BII)**.

Amphotericin B oral suspension (1 mL four times daily of the 100 mg/mL suspension) is sometimes effective among patients with oropharyngeal candidiasis who do not respond to itraconazole **(CIII)**. However, this product is not available in the United States.

Azole-refractory esophageal candidiasis also can be treated with posaconazole **(AII)**, anidulafungin **(BII)**, caspofungin **(CII)**, micafungin **(CII)**, or voriconazole **(CIII)**.

Preventing Recurrence

As with primary prophylaxis, the majority of HIV specialists do not recommend secondary prophylaxis (chronic maintenance therapy) for recurrent oropharyngeal or vulvovaginal candidiasis because of the effectiveness of therapy for acute disease, the low mortality associated with mucosal candidiasis, the potential for resistant *Candida* organisms to develop, the possibility of drug interactions, and the cost of prophylaxis **(DIII)**. However, if recurrences are frequent or severe, oral fluconazole can be used for either oropharyngeal **(BI)** or vulvovaginal **(CI)** candidiasis (*579–581*). A recent randomized clinical trial (*582*) has documented that the number of episodes of oropharyngeal candidiasis and other invasive fungal infections was statistically significantly lower in HIV patients with $CD4^+$ count <150 cells/μL when receiving continuous (three times a week) fluconazole versus episodic treatment of recurrences. This clinical trial also proved that the development of clinically significant resistance was not higher in the group of continuous prophylaxis than in the group with episodic administration of Fluconazole, provided that patients received ART.

The decision to use secondary prophylaxis should take into account the effect of recurrences on the patient's well-being and quality of life; the need for prophylaxis for other fungal infections; cost, toxicities, and most importantly, drug interactions (*589*).

For recurrent esophageal candidiasis, daily fluconazole can be used **(BI).** Oral posaconazole bid is also effective **(BII)**. However, potential azole resistance should be considered when long-term azoles are considered.

Secondary prophylaxis should be instituted in those patients with fluconazole-refractory oropharyngeal or esophageal candidiasis who have responded to echinocandins, voriconazole, or posaconazole therapy because of high relapse rate until ART produces immune reconstitution **(CI)**.

Discontinuing Secondary Prophylaxis (Chronic Maintenance Therapy)

In situations where secondary prophylaxis is instituted, no data support a recommendation regarding discontinuation. On the basis of experience with other OIs, discontinuing secondary prophylaxis when the $CD4^+$ count has risen to 200 cells/μL because of ART would be reasonable **(CIII)**.

Special Considerations During Pregnancy

Pregnancy increases the risk for vaginal colonization with *Candida* species. Diagnosis of oropharyngeal, esophageal, and vulvovaginal candidiasis is the same as among nonpregnant women.

Topical therapy is preferred for treatment of oral or vaginal candidiasis in pregnancy when possible **(BIII).** Single-dose, episodic treatment with fluconazole has not been associated with birth defects in humans. However, with chronic use of doses of fluconazole of 400 mg or higher in pregnancy, five cases of a syndrome of craniosynostosis, characteristic facies, digital synostosis, and limb contractures have been reported ("fluconazole embryopathy") (*590*). On the basis of these data, substitution of amphotericin B for high-dose fluconazole in the first trimester is recommended for invasive or refractory esophageal candidal infections **(AIII).** Neonates born to women on chronic amphotericin B at delivery should be evaluated for renal dysfunction and hypokalemia. Itraconazole has been teratogenic in animals at high doses, but the metabolic mechanism accounting for these defects is not present in humans, so data are not applicable. Case series in humans do not suggest an increased risk for birth defects with itraconazole, but experience is limited. Posaconazole was associated with skeletal abnormalities in rats at doses similar to human levels and was embryotoxic in rabbits. No human data are available for posaconazole. Voriconazole is FDA category D because of cleft palate and renal defects seen in rats and embryotoxicity in rabbits. No human data on use of voriconazole are available, so use in the first trimester is not recommended. Multiple anomalies are seen in animals with micafungin; ossification defects have been seen with anidulafungin and caspofungin. No human data are available for these drugs, and their use in human pregnancy is not recommended **(DIII).**

Chemoprophylaxis, either primary or secondary, against oropharyngeal, esophageal, or vaginal candidiasis using systemically absorbed azoles should not be initiated during pregnancy **(DIII),** and prophylactic azoles should be discontinued for HIV-infected women who become pregnant (**AIII).**

Cryptococcosis

Epidemiology

The majority of HIV-associated cryptococcal infections are caused by *Cryptococcus neoformans*; rarely, infection because of *Cryptococcus neoformans var. gattii* is recognized in the United States. Before the advent of potent ART, approximately 5%–8% of HIV-infected patients in developed countries acquired disseminated cryptococcosis (*591*). The incidence has declined substantially since then (*592*). The majority of cases are observed among patients who have $CD4^+$ counts of <50 cells/μL.

Clinical Manifestations

Among patients with HIV infection, cryptococcosis most commonly occurs as a subacute meningitis or meningoencephalitis with fever, malaise, and headache (*591*). Classic meningeal symptoms and signs, such as neck stiffness and photophobia, occur in only one fourth to one third of patients. Encephalopathic symptoms, including lethargy, altered mentation, personality changes, and memory loss, usually resulting from elevated intracranial pressure, occurs in small groups of patients.

Analysis of CSF usually demonstrates a mildly elevated serum protein; glucose ranging from low to normal; a pleocytosis consisting mostly of lymphocytes, although some patients have no cells; and a positive Gram or India ink stain for numerous yeasts. The opening pressure in the CSF is usually elevated, with pressures >20 cm H_2O occurring in up to 75% of patients. When cryptococcosis occurs in the HIV-infected patient, disseminated disease is common. Virtually any organ can be involved, and skin lesions mimicking molluscum contagiosum are frequently observed. In addition, isolated pulmonary infection is evident; symptoms and signs include cough and dyspnea in association with an abnormal chest radiograph.

Diagnosis

Cryptococcal antigen is almost invariably detected in CSF at high titer in patients with meningitis or meningoencephalitis. The serum cryptococcal antigen is also almost always positive in cases of CNS disease and in other instances of disseminated infection. As such, testing for serum cryptococcal antigen is a useful initial screening tool in diagnosing cryptococcosis in HIV-infected patients (*593*). Up to 75% of patients with HIV-associated cryptococcal meningitis have routine blood cultures positive for *C. neoformans*.

Preventing Exposure

HIV-infected persons cannot completely avoid exposure to *C. neoformans*. Limited epidemiologic evidence suggests that specific activities, including exposure to bird droppings, lead to an increased risk for infection.

Preventing Disease

Because the incidence of cryptococcal disease is low, routine testing of asymptomatic persons for serum cryptococcal antigen is not recommended **(DIII).**

Prospective, controlled trials indicate that fluconazole and itraconazole can reduce the frequency of primary cryptococcal disease among patients who have $CD4^+$ counts <50 cells/μL (*579,594*). However, the majority of HIV specialists recommend that antifungal prophylaxis not be used routinely to prevent cryptococcosis because of the relative infrequency of cryptococcal disease, lack of survival benefits associated with prophylaxis, possibility of drug interactions, potential antifungal drug resistance, and cost **(DIII).** The need for primary prophylaxis or suppressive therapy for other fungal infections

(e.g., candidiasis, histoplasmosis, or coccidioidomycosis) should be considered when making decisions concerning primary prophylaxis for cryptococcosis.

Treatment of Disease

The recommended initial standard treatment is amphotericin B deoxycholate, at a dose of 0.7 mg/kg daily, combined with flucytosine, at a dose of 100 mg/kg daily in four divided doses, for ≥2 weeks for those with normal renal function **(AI)**. Renal function should be monitored closely and the flucytosine dose adjusted appropriately for patients with renal impairment. The addition of flucytosine to amphotericin B during acute treatment is associated with more rapid sterilization of CSF (*595*,*596*). The combination of amphotericin B deoxycholate with fluconazole, 400 mg daily **(BII)**, is inferior to amphotericin B combined with flucytosine for clearing Cryptococcus from CSF but is more effective than amphotericin B alone **(BII)** (*597*).

Lipid formulations of amphotericin B also are effective and should be considered for patients who experience renal dysfunction during therapy or have a likelihood of having renal failure. The optimal dose of lipid formulations of amphotericin B has not been determined. An unpublished study demonstrated that liposomal amphotericin B (AmBisome®) at a dose of 6 mg/kg daily had an improved outcome over 3 mg/kg daily (*598*). The noncomparative CLEAR study used a mean dose of amphotericin B lipid complex (ABLC) of 4.4 mg/kg daily to treat cryptococcosis (*599*). In an Australian study, a 3-week course of liposomal amphotericin B (AmBisome®) at 4 mg/kg daily resulted in more rapid sterilization of CSF than amphotericin B deoxycholate at 0.7 mg/kg daily (*600*). On the basis of these data, a dose of 4–6 mg/kg daily for lipid formulations of amphotercin B is recommended **(AII).**

Fluconazole (400–800 mg daily) combined with flucytosine is an alternative to amphotericin B plus flucytosine (*598*), but is inferior to amphotericin B (*601*) and is recommended only for persons who are unable to tolerate or unresponsive to standard treatment **(CII).**

After at least a 2-week period of successful induction therapy, defined as substantial clinical improvement and a negative CSF culture after repeat lumbar puncture, amphotericin B and flucytosine may be discontinued and follow-up therapy initiated with fluconazole 400 mg daily **(AI).** This therapy should continue for 8 weeks **(AI)** (*595,596,602*). Itraconazole is an acceptable though less effective alternative **(BI)** (*602*). Limited data are available for the newer triazoles, voriconazole and posaconazole, as either primary or follow-up therapy for patients with cryptococcosis. Voriconazole should be used cautiously with HIV PIs and efavirenz.

Monitoring and Adverse Events, Including Immune Reconstitution Inflammatory Syndrome (IRIS)

Increased ICP can cause clinical deterioration despite a microbiologic response and is more likely if the CSF opening pressure is >20 cm H_2O (*596,603*). In one large clinical trial, 93% of deaths that occurred within the first 2 weeks of therapy and 40% of deaths that occurred within weeks 3–10 were associated with increased ICP (*603*).

At time of diagnosis, all patients with cryptococcal meningitis should have their opening pressure measured in the lateral decubitus position with good manometrics assured; normal values are <25 cm H_20. Patients with confusion, blurred vision, papilledema, lower extremity clonus, or other neurologic signs of increased ICP should be managed using measures to decrease ICP. Daily lumbar punctures are usually recommended for initial management. One approach is to remove a volume (typically 20–30 mL) of CSF that halves the opening pressure (*604*). CSF shunting should be considered for patients in whom daily lumbar punctures are no longer tolerated or whose signs and symptoms of cerebral edema are not being relieved **(BIII).** Corticosteroids, mannitol, and acetazolamide are not recommended **(DIII).**

After the initial 2 weeks of treatment, a repeat lumbar puncture should be performed to ensure the organism has been cleared from the CSF, even among those who have improved after the initial 2 weeks of treatment. Positive CSF cultures after 2 weeks of therapy are predictive of future relapse and typically less favorable clinical outcomes. If new symptoms or clinical findings occur later, a repeat lumbar puncture, with measurement of opening pressure and CSF culture, should be performed.

Patients treated with amphotericin B should be monitored for dose-dependent nephrotoxicity and electrolyte disturbances. Preinfusion administration of 500 mL of normal saline appears to reduce the risk for nephrotoxicity during treatment. Infusion-related adverse reactions may be ameliorated by pretreatment with acetaminophen and diphenhydramine; in rare cases, glucocorticosteroids administered approximately 30 minutes before the infusion might be required **(CIII).**

Patients receiving flucytosine should have flucytosine blood levels monitored to prevent bone marrow suppression and gastrointestinal toxicity; peak serum levels, which occur 2 hours after an oral dose, should not exceed 75 μg/mL. Persons treated with fluconazole should be monitored for hepatotoxicity.

An estimated 30% of patients with cryptococcal meningitis and HIV infection experience IRIS after initiation or reinitiation of ART (*605*). Patients who have cryptococcal IRIS are more likely to be antiretroviral naïve and have higher HIV RNA levels. Appropriate management of IRIS is to continue

ART and antifungal therapy **(AII).** In patients with severely symptomatic IRIS, short-course glucocorticosteroids are recommended by certain specialists **(BIII).** Delaying the initiation of potent ART might be prudent, at least until the completion of induction therapy (the first 2 weeks) for severe cryptococcosis, especially if patients have elevated ICP **(CIII).**

Management of Treatment Failure

Treatment failure is defined as either the lack of clinical improvement after 2 weeks of appropriate therapy, including management of increased ICP, or relapse after an initial clinical response, defined as either a positive CSF culture and/or a rising CSF cryptococcal antigen titer with an associated compatible clinical picture. Although fluconazole resistance has been reported with *C. neoformans,* it is rare in the United States (*606*). At this time, susceptibility testing is not recommended routinely **(DII).**

The optimal therapy for patients with treatment failure has not been established. For those initially treated with fluconazole, therapy should be changed to amphotericin B, with or without flucytosine, and continued until a clinical response occurs (**BIII**). Liposomal amphotericin B (4–6 mg/kg/day) might have improved efficacy over the deoxycholate formulation (*600,607*) and should be considered in treatment failures **(AII)**. Higher doses of fluconazole in combination with flucytosine also might be useful **(BIII)**. Caspofungin and other echinocandins have no in vitro activity against *Cryptococcus spp*. and no role in the clinical management of these patients. The newer triazoles, posaconazole and voriconazole, have activity against *Cryptococcus spp*. in vitro and might have a role in therapy.

Preventing Recurrence

Patients who have completed the initial 10 weeks of therapy for acute cryptococcosis should be administered chronic maintenance therapy with fluconazole 200 mg daily, either lifelong or until immune reconstitution occurs as a consequence of ART (**AI**). Itraconazole is inferior to fluconazole for preventing relapse of cryptococcal disease **(BI)** (*608,609*)**.**

Discontinuing Secondary Prophylaxis (Chronic Maintenance Therapy)

The risk for recurrence of cryptococcosis appears low when patients have successfully completed a course of initial therapy, remain asymptomatic with regard to signs and symptoms of cryptococcosis, and have a sustained increase (i.e., >6 months) in their CD4+ counts to ≥200 cells/μL after ART. The numbers of such patients who have been evaluated remain limited. In a European study, none of 39 subjects whose antifungal therapy was discontinued had a recurrence of cryptococcosis. The median CD4+ count of this cohort was 239 cells/μL, the median HIV RNA concentration was <500 copies/mL, and the median time on potent ART was 25 months (610). A prospective randomized study of 60 patients in Thailand documented no cases of recurrence after 48 weeks when the CD4+ count was >100 cells/μL and HIV RNA was undetectable for 3 months (*611*). On the basis of two published studies and inference from data regarding safety of discontinuing secondary prophylaxis for other OIs during advanced HIV disease, discontinuing chronic maintenance therapy among such patients who have successfully completed a course of intial therapy when the CD4+ count is consistently >200 cells/μL is reasonable **(BII)** (*612*). Certain HIV specialists would perform a lumbar puncture to determine if the CSF is culture negative and antigen negative before stopping therapy even if patients are asymptomatic **(CIII)**. Maintenance therapy should be reinitiated if the CD4+ count decreases to <200 cells/μL **(AIII)**.

Special Considerations During Pregnancy

The diagnosis and treatment of cryptococcal infections during pregnancy is similar to that in nonpregnant adults with the following considerations regarding the use of antifungal during pregnancy. Because of their risk for teratogenicity, azole antifungals should be avoided during the first trimester of pregnancy **(EII).** Neonates born to women on chronic amphotericin B at delivery should be evaluated for renal dysfunction and hypokalemia.

Histoplasmosis

Epidemiology

Histoplasmosis is caused by the dimorphic fungus *Histoplasma capsulatum*. In the United States, infection is common in several regions where the disease is endemic, especially the Ohio and Mississippi River Valleys. It is also endemic in Latin America, including Puerto Rico. Among persons with HIV infection residing in areas in which histoplasmosis is endemic, symptomatic disease occurs at an annual incidence approaching 5%. Environmental exposure, positive *Histoplasma* serology, and a CD4+ count ≤150 cells/μL are associated with an increased risk for symptomatic illness (*613*).

Virtually all cases of primary histoplasmosis are acquired by inhalation of microconidia from the mycelial phase of the organism. Asymptomatic dissemination of infection beyond the lungs is common and cellular immunity is critical in controlling infection. Reactivation of a silent focus of infection that was acquired years earlier can occur when cellular immunity wanes and is the presumed mechanism for disease occurrence in nonendemic areas. The incidence of symptomatic

histoplasmosis in patients with HIV infection appears to have declined since the use of potent ART.

Clinical Manifestations

Disseminated histoplasmosis usually occurs in patients with CD4⁺ counts ≤150 cells/μL (*614*). Common clinical manifestations include fever, fatigue, weight loss, hepatosplenomegaly, and lymphadenopathy (*615*). Cough, chest pain, and dyspnea occur in approximately 50% of patients (*614*). CNS, gastrointestinal, and cutaneous manifestations occur in a smaller percentage (*670*), and <10% of patients experience shock and multi-organ failure. Other anatomic sites are less commonly involved. Patients with CNS histoplasmosis typically experience fever, headache, and, if brain involvement is present, seizures, focal neurological deficits, and changes in mental status (*614,616*). Gastrointestinal disease usually is manifested by diarrhea, fever, abdominal pain, and weight loss (*617*). For patients with CD4⁺ counts >300 cells/μL, symptoms and signs of histoplasmosis are often limited to the respiratory tract.

Diagnosis

Detection of *Histoplasma* antigen in blood or urine is a sensitive method for rapid diagnosis of disseminated histoplasmosis but is insensitive for pulmonary infection. Antigen is detected in the urine of 95% and serum of 85% of AIDS patients with disseminated histoplasmosis (*618*). In patients with severe disseminated histoplasmosis, peripheral blood smears can show the organisms engulfed by WBCs. Histopathologic examination of biopsy material from involved tissues demonstrates the characteristic 2–4 μm budding yeast and can provide a rapid diagnosis.

H. capsulatum can be cultured from blood, bone marrow, respiratory secretions, or other involved sites in >85% of patients with AIDS, but organisms might require several weeks to grow (*614,618*). Serologic tests are less useful than antigen assays in AIDS patients with disseminated histoplasmosis, but might be helpful in patients who have intact immune responses.

The diagnosis of meningitis can be difficult. A lymphocytic pleocytosis is usually associated with elevated protein and low glucose. Fungal stains are usually negative, and CSF cultures are positive in a minority of cases (*619*). *Histoplasma* antigen or anti-*Histoplasma* antibodies can be detected in CSF in up to 70% of cases and either is diagnostic. For some patients, none of these tests are positive, and a presumptive diagnosis of *Histoplasma* meningitis is appropriate if the patient has disseminated histoplasmosis and findings of CNS infection not explained by another cause.

Preventing Exposure

Although HIV-infected persons living in or visiting areas in which histoplasmosis is endemic cannot completely avoid exposure, those whose CD4⁺ counts are ≤150 cells/μL should avoid activities known to be associated with increased risk **(CIII).** Such activities include creating dust when working with surface soil; cleaning chicken coops that are contaminated with droppings; disturbing areas contaminated with bird or bat droppings; cleaning, remodeling, or demolishing old buildings; and exploring caves **(CIII).**

Preventing Disease

Initiating Primary Prophylaxis

Data from a prospective, randomized, controlled trial indicate that itraconazole can reduce the frequency of histoplasmosis among patients who have advanced HIV infection and who live in areas in which histoplasmosis is highly endemic (*594*). However, no survival benefit was observed among persons receiving itraconazole.

Prophylaxis with itraconazole at a dose of 200 mg daily can be considered for patients with CD4⁺ counts ≤150 cells/μL who are at high risk because of occupational exposure or who live in a community with a hyperendemic rate of histoplasmosis (>10 cases/100 patient-years) **(CI).**

Discontinuing Primary Prophylaxis

If used, primary prophylaxis can be discontinued once peripheral blood CD4⁺ counts are >150 cells/μL for 6 months in patients on potent ART **(BIII).** Prophylaxis should be restarted if the CD4⁺ counts fall to ≤150 cells/μL **(CIII).**

Treatment of Disease

Patients with moderately severe to severe disseminated histoplasmosis should be treated with an IV lipid formulation of amphotericin B for ≥2 weeks (or until they improve clinically) followed by oral itraconazole (200 mg three times daily for 3 days and then 200 mg twice daily for a total of >12 months) **(AI)** (*620,621*).

In a randomized clinical trial, liposomal amphotericin B at 3.0 mg/kg daily was more effective than standard amphotericin B deoxycholate at 0.7 mg/kg daily (*620*), inducing a more rapid and more complete response, lowering mortality, and reducing toxicity. Substitution with ABLC at 5.0 mg/kg daily may be an alternative because of cost or tolerability **(CIII).**

In patients with less severe disseminated histoplasmosis, oral itraconazole at 200 mg three times daily for 3 days followed by 200 mg twice daily is appropriate initial therapy **(AII)** (*622*). The liquid formulation of intraconazole is preferred, owing to better absorption and fewer food interactions.

For persons with confirmed meningitis, liposomal amphotericin B should be administered as initial therapy for 4–6 weeks at a dosage of 5 mg/kg daily. This should be followed by maintenance therapy with itraconazole at a dose of 200 mg two or three times daily for a total of ≥1 year and until resolution of abnormal CSF findings **(AII)** (*616*).

Posaconazole has been reported in some salvage studies to be of some benefit (*623*). Fluconazole has limited to no activity against histoplasmosis and should not be used. The role of other azoles, including voriconazole, is not clear. Voriconazole should be used cautiously with HIV PIs and efavirenz. No published data exist regarding the use of echinocandins for treating patients with histoplasmosis.

Acute pulmonary histoplasmosis in an HIV-infected patient with intact immunity, as indicated by a CD4⁺ count >300 cells/μL, should be managed in a manner similar to that used for a nonimmunocompromised host **(AIII)** (*621*).

Monitoring and Adverse Events, Including Immune Reconstitution Inflammatory Syndrome (IRIS)

Serial monitoring of serum or urine for *Histoplasma* antigen is useful for determining response to therapy. A rise in level is suggestive of a relapse **(AIII).** Because absorption of itraconazole can be erratic, serum itraconazole levels should be obtained at least once in all patients to ensure adequate absorption **(AIII).** The serum concentration should be >1 μg/mL, ideally drawn for reasons of consistency as a trough level after at least 7 days on the current regimen. Itraconazole solution is recommended over the capsule formulation because absorption is improved, but this has not been studied specifically in AIDS patients.

IRIS has been reported uncommonly in patients with histoplasmosis (*605,624,625*). ART should not be withheld because of concern for the possible development of IRIS **(AIII).**

Management of Treatment Failure

Posaconazole solution at 800 mg daily was recently reported to be successful in three patients with HIV infection whose other previous therapies had failed (*623*). Voriconazole has been used in several transplant recipients and in one patient with AIDS who failed or could not tolerate therapy with other agents (*626,627*). Cross resistance between fluconazole and voriconazole has been noted in vitro *(628*).

Preventing Recurrence

Long-term suppressive therapy with itraconazole (200 mg daily) should be administered for patients with severe disseminated or CNS infection **(AII)** and in patients who relapse despite receipt of appropriate therapy **(CIII).** Fluconazole 800 mg daily is less effective than itraconazole **(CII)** (*629*). The role of voriconazole and posaconazole is not clear, but both have been used successfully in patients with histoplasmosis (*623,626*).

Discontinuing Secondary Prophylaxis (Chronic Maintenance Therapy)

An AIDS Clinical Treatment Group (ACTG)-sponsored study reported that discontinuing itraconazole was safe for patients who have been treated for histoplasmosis and who have a good immunologic response to ART (*630*). In that trial, patients had received ≥1 year of itraconazole therapy, had negative blood cultures, Histoplasma serum antigen <2 units, CD4⁺ counts >150 cells/μL, and had been on ART for 6 months. No relapses were evident in 32 subjects who were followed for a median of 24 months (*630*). Thus, discontinuing suppressive azole therapy appears to be safe for patients who meet the criteria described above **(AI)**. Suppressive therapy should be resumed if the CD4⁺ count decreases to <150 cells/μL **(BIII)**.

Special Considerations During Pregnancy

Because of their risk for teratogenicity, azoles should not be used during the first trimester of pregnancy **(EII).** Neonates born to women on chronic amphotericin B at delivery should be evaluated for renal dysfunction and hypokalemia.

Coccidioidomycosis

Epidemiology

Coccidioidomycosis is caused by a soil-dwelling fungus that consists of two species, *Coccidioides immitis* and *C. posadasii*. Most cases in persons with HIV infection have been from the areas in which the disease is endemic, including the Southwestern United States and parts of Central and South America (*631*). However, sporadic cases have been diagnosed outside those areas, presumably as a result of reactivation of a previous infection.

Cellular immunity is critical in controlling coccidioidomycosis. Symptomatic coccidioidomycosis can occur in persons with normal CD4⁺ concentrations. In patients with no discernible immunodeficiency, disseminated disease occurs in <1%. Black and Filipino men appear to be at higher risk for disseminated disease, as do pregnant women who acquire coccidioidal infection in the second or third trimester.

In patients with HIV infection, immune response to *Coccidioides spp*. appears to wane with declining CD4⁺ counts and the risk for developing symptomatic disease in areas in which the disease is endemic increases when this count is <250 cells/μL or with a diagnosis of AIDS (*632*). Retrospective studies have suggested a decline in the incidence of coccidioidomycosis in the areas in which the disease is endemic since the introduction of ART (*633*).

Clinical Manifestations

Among persons with HIV infection, six common syndromes have been described (*634*). These are focal pneumonia, diffuse pneumonia (presenting as apparent PCP), cutaneous involvement, meningitis, liver or lymph node involvement, and positive coccidioidal serology tests without evidence of localized infection. Focal pneumonia is most common in those with $CD4^+$ counts >250 cells/μL, whereas the other syndromes usually occur in more immunosuppressed patients. Symptoms of meningitis are headache and progressive lethargy. The CSF profile demonstrates a low glucose with elevated protein and a lymphocytic pleocytosis.

Diagnosis

The diagnosis of coccidioidomycosis is confirmed by culture of the organism from clinical specimens or by demonstration of the typical spherule on histopathologic examination of involved tissue. Blood cultures are positive in a minority of patients, usually in those with diffuse pulmonary disease. Coccidioidal IgM and IgG serology, performed by EIA, immunodiffusion, or classical tube precipitin or complement fixation methodology, is useful in diagnosis although it may be less frequently positive among patients with low $CD4^+$ counts than among immunocompetent persons. Complement fixation IgG antibody is frequently detected in the CSF in coccidioidal meningitis and is useful in establishing this diagnosis. Culture of the CSF is positive in fewer than one third of patients with meningitis.

Preventing Exposure

Although HIV-infected persons cannot completely avoid activities involving extensive exposure to infection while living in or visiting areas in which *Coccidioides spp*. is endemic, they should avoid activities involving extensive exposure to disturbed native soil, such as occurs at building excavation sites or during dust storms **(CIII).**

Preventing Disease

Initiating Primary Prophylaxis

Within an area where the disease is endemic, a positive IgM or IgG serologic test indicates an increased risk for the development of active infection (*635*) and specialists would recommend treatment if the $CD4^+$ count is <250 cells/μL **(BIII).** Yearly testing for seronegative HIV-infected persons living in such regions is reasonable **(CIII).**

Although highly immunosuppressed patients (*633*) might benefit from primary prophylaxis, such therapy for HIV-infected persons without a positive IgM or IgG serologic test who live in the area where disease is endemic is not recommended **(DIII).** However, several clinicians would empirically provide chemoprophylaxis with either oral fluconazole 400 mg daily or itraconazole 200 mg bid if there were a positive IgM or IgG serologic test and the CD4 cell count was <250 cells/μL **(CIII).** Outside the region in which coccidiodomycosis is endemic, routine testing does not appear to be useful and should not be performed **(DIII).**

Discontinuing Primary Prophylaxis

If used, primary prophylaxis can be discontinued once peripheral blood $CD4^+$ counts are $\geq$250 cells/μL for 6 months **(CIII)**. Primary prophylaxis should be restarted if the $CD4^+$ count is <250 cells/μl **(BIII)**.

Treatment of Disease

For patients with clinically mild infection, such as focal pneumonia, or who have a positive coccidioidal serologic test alone, initial therapy with a triazole antifungal is appropriate **(BII).** Fluconazole or itraconazole at doses of 400 mg daily is recommended (*636,637*). Data are limited with regard to the newer triazoles, posaconazole and voriconazole, but these agents might be useful in cases that fail to respond to fluconazole or itraconazole. Voriconazole should be used cautiously with HIV PIs and efavirenz.

For patients with either diffuse pulmonary involvement or severely ill patients with extrathoracic disseminated disease, amphotericin B is the preferred initial therapy **(AII)** (*636*). Most experience has been with the deoxycholate formulation using 0.7–1.0 mg/kg daily as an initial dose. Data regarding lipid formulations of amphotericin B are limited, but these formulations are likely as effective.

Therapy with amphotericin B should continue until clinical improvement is observed. Certain specialists would use a triazole antifungal concurrently with amphotericin B and continue the triazole once amphotericin B is stopped **(BIII)** (*636*).

Treatment of patients with coccidioidal meningitis requires consultation with a specialist. Therapy should begin with a triazole antifungal. Fluconazole at a dose of 400–800 mg daily is preferred **(AII)** (*638*), but itraconazole has also been used successfully (*639*). Successful therapy with voriconazole (*640,641*) and posaconazole (*642*) has been described in case reports. Despite successful antifungal therapy, patients might develop hydrocephalus and require CSF shunting. In some instances, triazole antifungals are not effective. In such cases, intrathecal amphotericin B is recommended **(AIII).**

Monitoring and Adverse Events, Including Immune Reconstitution Inflammatory Syndrome (IRIS)

Monitoring the titer of the complement-fixing (CF) antibody is useful in assessing clinical response to therapy. This should be obtained every 12 weeks **(AIII).** A rise suggests

recurrence of clinical disease. IRIS has not been observed in coccidioidomycosis.

Management of Treatment Failure

Patients whose therapy with fluconazole or itraconazole fails might be candidates for newer triazoles, but data regarding both posaconazole and voriconazole are limited. In most such instances, IV amphotericin B, in combination with triazole therapy, is recommended.

Preventing Recurrence

Patients who complete initial therapy for coccidioidomycosis should be considered for lifelong suppressive therapy using either fluconazole 400 mg daily or itraconazole 200 mg twice daily **(AII).**

Discontinuing Secondary Prophylaxis (Chronic Maintenance Therapy)

Patients with focal coccidioidal pneumonia who have clinically responded to antifungal therapy appear to be at low risk for recurrence of coccidioidomycosis if their $CD4^+$ counts are >250 cells/μL and they are receiving ART. A reasonable plan for treating such patients is to discontinue secondary prophylaxis after 12 months of therapy **(CIII)** with continued monitoring for recurrence using serial chest radiographs and coccidioidal serology.

In patients with diffuse pulmonary disease or nonmeningeal disseminated coccidioidomycosis, relapses occur even in patients without HIV infection in 25%–33% of cases (*643,644*). Even in patients with $CD4^+$ counts >250 cells/μL on potent ART, therapy should be continued indefinitely **(AIII).** For patients with meningitis, relapses have occurred in 80% of patients in whom triazoles have been discontinued (*645*). On the basis of this evidence, therapy for coccidioidal meningitis should be lifelong **(AII).**

Special Considerations During Pregnancy

Coccidioidomycosis is more likely to disseminate if acquired during the second or third trimester of pregnancy (*646*). Because of their risk for teratogenicity, azoles should not be used during the first trimester of pregnancy **(EII).** Neonates born to women on chronic amphotericin B at delivery should be evaluated for renal dysfunction and hypokalemia. One problematic area is coccidioidal meningitis, in which the only alternative treatment is intrathecal amphotericin B. For such situations, the decision regarding choice of treatment should be made in consultation with the mother, infectious diseases consultant, and obstetrician.

Aspergillosis

Epidemiology

Invasive aspergillosis in the HIV-infected person is rare. It is most frequently caused by *Aspergillus fumigatus*, although certain cases are caused by *A. flavus*, *A. niger,* and *A. terreus*. Invasive aspergillosis occurs among patients with advanced HIV infection and was more common before the advent of ART (*647,648*). Specific risk factors include neutropenia, use of corticosteroids, exposure to broad-spectrum antibacterial therapy, and previous pneumonia or other underlying lung disease. Patients who have had HIV-associated aspergillosis typically have $CD4^+$ counts <100 cells/μL, a history of other AIDS-defining OIs, and are not receiving ART (*649*).

Clinical Manifestations

Invasive aspergillosis in the HIV-infected patient is evidenced most commonly as a respiratory illness that can be a necrotizing pneumonia or a tracheobronchitis (*650*). Symptoms of invasive pneumonia are fever, cough, dyspnea, chest pain, hemoptysis, and hypoxemia; the chest radiograph might demonstrate a diffuse, focal, or cavitary infiltrate. A "halo" of low attentuation surrounding a pulmonary nodule or an "air-crescent" on CT scan of the lung is suggestive of disease. Tracheobronchitis is associated with fever, cough, dyspnea, stridor, and wheezing. Bronchoscopic examination demonstrates multiple ulcerative or plaque-like lesions adherent to the tracheal wall (*651*). Extrapulmonary forms of invasive aspergillosis include sinusitis, cutaneous disease, osteomyelitis, and CNS infection (*652*).

Diagnosis

The diagnosis of pulmonary aspergillosis is usually based on either 1) the repeated isolation of *Aspergillus spp*. from cultures or respiratory secretions or 2) the finding of dichotomously branching septate hyphae consistent with *Aspergillus spp*. in respiratory or other samples in association with a compatible clinical syndrome. Histological evidence of tissue invasion by hyphae with a positive culture for *Aspergillus spp*. represents a definite diagnosis.

Newer tests based on circulating fungal antigen have been employed to diagnose aspergillosis. These have not been formally evaluated in patients with HIV infection. A sandwich ELISA test for galactomannan, a major fungal cell wall antigen, can be used on serum and bronchoalveolar lavage fluid (*653*). Although sensitivity and specificity appear reasonable, the test has yielded both false-positive and -negative results and is currently recommended for screening for invasive aspergillosis primarily in stem-cell transplant recipients.

Preventing Exposure

Aspergillus spp. are ubiquitous in the environment, and exposure is unavoidable. Avoiding particularly dusty environments is prudent, especially in areas such as those created by construction because spore counts might be higher in such settings.

Preventing Disease

No data on the prevention of primary aspergillosis in HIV-infected patients exists, although posaconzaole has been reported to be effective among patients with hematologic malignancy and neutropenia (*654*).

Treatment of Disease

Treatment of aspergillosis in the HIV-infected population has not been examined systematically. The recommended treatment for invasive aspergillosis in patients without HIV infection is voriconazole (*655*). Voriconazole is the drug of choice but should be used cautiously with HIV PIs and efavirenz **(BIII).** Amphotericin B deoxycholate at 1 mg/kg daily or lipid-formulation amphotericin B at 5 mg/kg daily are alternatives **(AIII),** as is caspofungin at 50 mg daily (**BII**) and posaconazole **(BII).** Other echinocandins, such as micafungin and anidulafungin, are reasonable alternatives. Posaconazole also has proven to be useful in patients with invasive aspergillosis without HIV infection (*656*) but is not approved for treatment of aspergillosis. The length of therapy is not established but should continue at least until the peripheral blood CD4$^+$ count is >200 cells/μL and there is evidence of clinical response.

Monitoring and Adverse Events, Including Immune Reconstitution Inflammatory Syndrome (IRIS)

IRIS has rarely been reported to occur in patients with invasive aspergillosis (*657*).

Management of Treatment Failure

The overall prognosis is poor among patients with advanced immunosuppression and in the absence of effective ART. No data are available to guide recommendations for the management of treatment failure. If voriconazole was used initially, substitution with amphotericin B, posaconazole, or echinocandins might be considered; the amphotericin B or echinocandins would be a reasonable choice for those who began therapy with voriconazole or posaconazole **(BIII).**

Preventing Recurrence

No data are available to base a recommendation for or against chronic maintenance or suppressive therapy among patients who have successfully completed an initial course of treatment **(CIII).**

Special Considerations During Pregnancy

Because of their risk for teratogenicity, azoles should not be used during the first trimester of pregnancy **(EII).** (See mucocutaneous candidiasis). Neonates born to women on chronic amphotericin B at delivery should be evaluated for renal dysfunction and hypokalemia.

Cytomegalovirus Disease

Epidemiology

Cytomegalovirus (CMV) is a double-stranded DNA virus in the Herpesvirus family that can cause disseminated or localized end-organ disease among patients with advanced immunosuppression. Most clinical disease occurs in previously infected (seropositive) persons and so represents either reactivation of latent infection or reinfection with a novel strain.

End-organ disease caused by CMV occurs among persons with advanced immunosuppression, typically those with CD4$^+$ counts <50 cells/μL, who are either not receiving or have failed to respond to ART (*658–660*). Other risk factors include previous OIs and high plasma HIV RNA levels (>100,000 copies/mL).

Before potent ART, an estimated 30% of patients with AIDS experienced CMV retinitis some time between the diagnosis of AIDS and death (*658–660*). The incidence of new cases of CMV end-organ disease has declined by 75%–80% with the advent of ART and now is estimated to be <6 cases per 100 person-years (*661*). For those with established CMV retinitis, recurrence of active lesions occurs at a rate of 0.58/person-year for those with CD4$^+$ cells <50 cells/μL, a rate substantially lower than that seen in the pre-ART era. However, even for those with immune recovery sufficient to discontinue anti-CMV therapy (i.e., >100 cells/μL), relapse of the retinitis occurs at a rate of 0.03/person-year and can occur at CD4$^+$ counts as high as 1,250 cells/μL (*662*). Therefore, whether anti-CMV therapy is continued, regular ophthalmologic follow-up is needed.

Clinical Manifestations

Retinitis is the most common clinical manifestation of CMV end-organ disease. CMV retinitis occurs as unilateral disease in two thirds of patients at presentation, but in the absence of therapy or immune recovery, viremic dissemination results in bilateral disease in the majority of patients (*663*). For patients with unilateral CMV retinitis and CD4$^+$ count <50 cells/μL, rates of contralateral disease approach those of the pre-ART era (*663*).

Peripheral retinitis might be asymptomatic or present with floaters, scotomata, or peripheral visual field defects. Central retinal lesions or lesions impinging on the macula or optic

nerve are associated with decreased visual acuity or central field defects. CMV retinitis is a full-thickness necrotizing retinitis, and the characteristic ophthalmologic appearance is that of fluffy yellow-white retinal lesions, with or without intraretinal hemorrhage, and with little inflammation of the vitreous unless immune recovery with potent ART intervenes (*658*). Blood vessels near the lesions might appear to be sheathed. Occasionally, CMV retinitis lesions, particularly peripheral lesions, might have a more granular appearance.

In the absence of ART or specific anti-CMV therapy, retinitis invariably progresses, usually within 10–21 days after presentation. Progression of retinitis occurs in "fits and starts" and causes a characteristic brushfire pattern, with a granular, white leading edge advancing before an atrophic gliotic scar (*672*).

Colitis occurs in 5%–10% of persons with AIDS and CMV end-organ disease (*659*). The most frequent clinical manifestations are fever, weight loss, anorexia, abdominal pain, debilitating diarrhea, and malaise. Extensive mucosal hemorrhage and perforation can be life-threatening complications.

Esophagitis caused by CMV, which occurs in <5%–10% of persons with AIDS who experience CMV end-organ disease, causes fever, odynophagia, nausea, and occasionally mid-epigastric or retrosternal discomfort. CMV pneumonitis is uncommon. CMV neurologic disease causes dementia, ventriculoencephalitis, or ascending polyradiculomyelopathy (*664*). Patients with dementia typically have lethargy, confusion, and fever, mimicking that of HIV dementia. CSF typically demonstrates lymphocytic pleocytosis (although a mixture of neutrophils and lymphocytes might be evident), low-to-normal glucose levels, and normal-to-elevated protein levels. Patients with ventriculoencephalitis have a more acute course, with focal neurologic signs, often including cranial nerve palsies or nystagmus, and rapid progression to death. Periventricular enhancement of CT or MRI images is indicative of CMV ventriculoencephalitis rather than HIV-related neurologic disease. CMV polyradiculomyelopathy causes a Guillian-Barre–like syndrome characterized by urinary retention and progressive bilateral leg weakness. The clinical symptoms usually progress during several weeks to include loss of bowel and bladder control and to flaccid paraplegia. A spastic myelopathy has been reported and sacral paresthesia might occur. The CSF usually demonstrates a neutrophilic pleocytosis (usually 100–200 neutrophils/μL and some erythrocytes) accompanied by hypoglycorrhachia and elevated protein levels.

Diagnosis

CMV viremia can be detected by PCR or antigen assays and is usually observed in end-organ disease, but viremia also might be present in the absence of end-organ disease (*664-669*). The presence of serum antibodies to CMV is not diagnostically useful, although a negative IgG antibody level indicates that CMV is unlikely to be the cause of the disease process.

The diagnosis of CMV retinitis is usually made based on recognition of characteristic retinal changes observed through a dilated pupil during an ophthalmoscopic examination performed by an experienced ophthalmologist. Diagnosis by such clinical examination has a 95% positive predictive value. In rare cases, diagnosis might be difficult and PCR of vitreous for CMV and other pathogens might be valuable in the differential diagnosis.

Demonstration of mucosal ulcerations on endoscopic examination combined with colonoscopic or rectal biopsy with histopathologic demonstration of characteristic intranuclear and intracytoplasmic inclusions is required for the diagnosis of CMV colitis (*659*). The diagnosis of CMV esophagitis is established by the presence of extensive large, shallow ulcers of the distal esophagus and biopsy evidence of intranuclear inclusion bodies in the endothelial cells with an inflammatory reaction at the edge of the ulcer (*659*).

Culturing CMV from a biopsy or cells brushed from the colon or the esophagus is not sufficient to establish the diagnosis of CMV colitis or esophagitis in the absence of histopathologic changes because certain persons with low $CD4^+$ counts might be viremic and have positive cultures for CMV in the absence of clinical disease (*669*).

Diagnosis of CMV pneumonitis should take into account pulmonary interstitial infiltrates, identification of multiple CMV inclusion bodies in lung tissue, and the absence of other pathogens that are more commonly associated with pneumonitis evident in this population (*667*). CMV neurologic disease is diagnosed on the basis of a compatible clinical syndrome and the presence of CMV in CSF or brain tissue (*660,668*). Detection of CMV is enhanced by PCR (*665,668*).

Preventing Exposure

HIV-infected persons who belong to groups at risk with relatively low seroprevalence rates for CMV and who, therefore, cannot be presumed to be seropositive should be tested for antibody to CMV **(BIII)**. These groups include patients who have not had contact with MSM or used injection drugs. HIV-infected adolescents and adults should be advised that CMV is shed in semen, cervical secretions, and saliva and that latex condoms must always be used during sexual contact to reduce the risk for exposure to CMV and to other sexually transmitted pathogens **(AII)**.

HIV-infected adults and adolescents who provide child care or parents of children in day care facilities should be informed that they are at increased risk for acquiring CMV infection **(BI).** Similarly, parents and other caretakers of HIV-infected children should be advised of the increased risk to children at

these centers **(BIII).** Risk for acquiring CMV infection can be diminished by optimal hygienic practices (e.g., hand-washing and use of latex gloves) **(AII).**

HIV-exposed infants and infected children, adolescents, and adults who are seronegative for CMV and who require blood transfusion should be administered only CMV antibody-negative or leukocyte-reduced cellular blood products in nonemergency situations **(BIII).**

Preventing Disease

CMV end-organ disease is best prevented using ART to maintain the $CD4^+$ count >100 cells/μL. Although oral valganciclovir would likely prevent the occurrence of CMV retinititis in patients with $CD4^+$ counts <50 cells/μL, such therapy is not usually recommended because of cost, the potential to induce CMV resistance, the utility of treating disease when it occurs, and the lack of demonstrated survival advantage **(DI)**. The primary method for preventing severe CMV disease is recognizing the early manifestations of the disease. Patients should be made aware of the importance of increased floaters in the eye and should be advised to assess their visual acuity regularly by using simple techniques (e.g., reading newsprint) **(BIII).** Regular funduscopic examinations performed by an ophthalmologist are recommended by certain specialists for patients with low (e.g., <50 cells/μL) $CD4^+$ counts **(CIII).**

Natural history studies in the era of ART indicate that CMV viremia can be detected by PCR on at least one occasion in approximately 30% of those whose $CD4^+$ counts remain <100 cells/μL (*669*). Such detection of CMV infection by PCR correlates with the development of future CMV disease and death (*669*). Furthermore, evidence from a cohort study indicates that patients with CMV retinitis administered systemic therapy had substantially reduced mortality (*671*). These observations suggest that pre-emptive anti-CMV treatment administered to patients who have evidence of active infection but who have not yet exhibited end-organ disease could be a therapeutic strategy for preventing CMV end-organ disease. Unless future studies document that clinical benefit can be obtained from pre-emptive therapy, the treatment of patients with CMV viremia in the absence of organ system involvement is not recommended **(DII).**

Treatment of Disease

Oral valganciclovir, IV ganciclovir, IV ganciclovir followed by oral valganciclovir, IV foscarnet, IV cidofovir, and the ganciclovir intraocular implant coupled with valganciclovir are all effective treatments for CMV retinitis **(AI)** (*672–677*). Systemic therapy has been documented to reduce morbidity in the contralateral eye (*710*). This therapy should be considered when choosing among oral, IV, and local options. The choice of initial therapy for CMV retinitis should be individualized based on the location and severity of the lesion(s), the level of underlying immune suppression, and other factors such as concomitant medications and ability to adhere to treatment (**AIII**). No one regimen has been proven in a clinical trial to have superior efficacy related to protecting vision, and thus clinical judgment must be used when choosing a regimen (*673–677*). Forms of ganciclovir most often are the first choice for CMV infection or disease. Certain clinical trials were conducted with oral ganciclovir, a preparation that was poorly bioavailable and is no longer marketed. Instead, the prodrug valganciclovir, which is the valine ester of ganciclovir, is administered orally to deliver ganciclovir. In these guidelines, references to oral ganciclovir have been deleted and the equivalent dose of valganciclovir has been substituted.

The ganciclovir intraocular implant plus oral valganciclovir is superior to once-daily IV ganciclovir (and presumably to once-daily oral valganciclovir) for preventing relapse of retinitis **(AI)** (*673–677*). For this reason, certain HIV specialists recommend the intraocular implant plus valganciclovir as the preferred initial therapy for patients with immediate sight- threatening lesions (adjacent to the optic nerve or fovea); for patients with small peripheral lesions oral valganciclovir alone may be adequate **(BII).** Certain ophthalmologists recommend an initial intravitreous injection of ganciclovir at the time CMV retinitis is diagnosed to deliver a high local concentration of ganciclovir to the eye immediately, until the ganciclovir implant can be placed **(CIII).**

Because ART can control CMV retinitis without anti-CMV therapy in patients who experience immune recovery, some clinicians might consider not treating small peripheral CMV lesions with anti-CMV therapy in ART-naïve patients. However, complications of CMV retinitis, including immune recovery retinitis and retinal detachment, are more common in patients with larger CMV lesions, and ART might take 3–6 months to fully control HIV replication and stimulate sufficient immune recovery to control the retinitis. Furthermore, consistent with natural history studies that associated CMV viremia with increased mortality in the pre- and current ART era (*669,678,679*), evidence indicates that anti-CMV therapy decreases mortality among patients with CMV retinitis and immune compromise (*671*). Therefore, even in ART-naïve patients with small peripheral lesions, treatment with systemic anti-CMV therapy, such as valganciclovir for the initial 3–6 months until ART has induced immune recovery, will likely be beneficial **(BII).**

For patients who have colitis or esophagitis, a majority of HIV specialists would recommend IV ganciclovir or foscarnet (or with oral valganciclovir if symptoms are not severe enough to interfere with oral absorption) for 21–28 days or until signs

and symptoms have resolved **(BII)**. Certain HIV specialists also would withhold therapy unless moderate-to-severe symptoms justify the use of systemic treatment if ART is to be initiated soon or can be optimized **(BIII)**.

Criteria for establishing that CMV is the cause of pneumonitis and pulmonary dysfunction have been difficult to establish. If CMV is considered the cause of pulmonary dysfunction based on histology or cytology, treatment with IV ganciclovir, foscarnet, or cidofovir is logical, although few data establish that such therapy affects outcome **(CIII).**

For neurological disease, initiating therapy promptly is critical for an optimal clinical response. Although combination treatment with ganciclovir and foscarnet might be preferred as initial therapy to stabilize disease and maximize response (**BII**), this approach is associated with substantial rates of adverse effects, and optimal treatment for neurologic disease if ART can be optimized has not been established.

No data are available to demonstrate that starting ART among treatment-naïve patients with CMV retinitis would have an adverse effect on retinitis, gastrointestinal disease, or pneumonitis. Therefore, initiation of appropriate ART should be administered to those with acute CMV retinitis, gastrointestinal disease, or pneumonitis **(BIII).** Although no data indicate that IRIS worsens CMV neurologic disease syndromes, because of the localized morbidity that might occur with such an inflammatory reaction, a delay in initiating ART in this setting until clinical improvement occurs might be prudent **(CIII).**

Monitoring and Adverse Events, Including Immune Reconstitution Inflammatory Syndrome (IRIS)

Management of CMV retinitis requires close monitoring by an experienced ophthalmologist and the primary clinician. Consideration should be given to both treating the infected eye and preventing infection in the contralateral eye using systemic treatment (*663,680*).

Indirect ophthalmoscopy through a dilated pupil should be performed at the time of diagnosis of CMV retinitis, after completion of induction therapy, 1 month after the initiation of therapy, and monthly thereafter while the patient is on anti-CMV treatment **(AIII).** Monthly fundus photographs, using a standardized photographic technique that documents the appearance of the retina, provide the optimum method for following patients and detecting early relapse **(AIII).** For patients who have experienced immune recovery, the frequency of ophthalmologic follow-up can be decreased to every 3 months **(AIII).** Because relapse of retinitis might still occur among some patients with immune recovery, ophthalmologic follow-up might be indicated; however, the optimal timing and interval of such follow-up has not been established.

Adverse effects of ganciclovir include neutropenia, thrombocytopenia, nausea, diarrhea, and renal dysfunction. Adverse effects of foscarnet include anemia, nephrotoxicity, and electrolyte abnormalities. For patients receiving ganciclovir or foscarnet, monitoring of complete blood counts and serum electrolytes and renal function should be performed twice weekly during induction therapy and once weekly thereafter **(AIII).** Cidofovir is associated with dose-related nephrotoxicity and hypotony. For patients receiving IV cidofovir, blood urea nitrogen, creatinine, and urinalysis should be performed before each infusion; administration of the drug is contraindicated if renal dysfunction or proteinuria is detected. Even in the absence of retinitis with other CMV end-organ disease, periodic ophthalmologic examinations are needed to monitor for cidofovir-associated uveitis when this agent is used.

Immune recovery uveitis (IRU) is an ocular form of IRIS caused by an immunologic reaction to CMV, characterized by inflammation in the anterior chamber or vitreous in the setting of immune recovery after initiation of ART and is usually observed among those patients with a substantial rise in $CD4^+$ counts in the first 4–12 weeks after initiation of ART (*681–685*). Ocular complications of uveitis include macular edema and the development of epiretinal membranes, which can cause loss of vision. Treatment usually requires periocular corticosteroids or short courses of systemic corticosteroids. Estimated response rates are 50%. One uncontrolled case series suggested that IRU (or CMV retinitis-associated IRIS) might respond to oral valganciclovir (*686*).

Management of Treatment Failure

For patients without immune recovery after initiation of ART and who are receiving chronic maintenance therapy with systemic anti-CMV drugs, relapse of retinitis is likely to occur. Although drug resistance might be responsible for some episodes of relapse, early relapse is most often caused by the limited intraocular penetration of systemically administered drugs (*687–689*). Because it results in greater drug levels in the eye, the placement of a ganciclovir implant in a patient who has relapsed while receiving systemic treatment (IV ganciclovir or oral valganciclovir) is usually recommended and often will control the retinitis for 6–8 months until the implant requires replacement **(BIII)** (*690,691*)**.**

When patients relapse while receiving maintenance therapy, reinduction with the same drug followed by reinstitution of maintenance therapy can control retinitis, although for progressively shorter periods (*692*), and the majority of specialists recommend this approach for initial treatment of patients who experience relapsed disease (**AII**). Changing to an alternative drug at the time of first relapse typically does not result in superior control of the retinitis but should be

considered if drug resistance is suspected or if side effects or toxicities interfere with optimal courses of the initial agent (**AIII**) (*692*). The combination of ganciclovir and foscarnet is usually superior to systemic therapy with either agent alone and might be considered for patients with relapsed retinitis (*692*); however, this combination of drugs is accompanied by greater toxicity (**BI**).

Drug resistance occurs among patients receiving long-term therapy (*693–696*). Reported rates in the pre-ART era were approximately 25% per person-year (*693,697,698*) and reported rates are similar for ganciclovir, foscarnet, and cidofovir (*693,694*). In the ART era, the rate of resistance appears to be less, approximately 10% per person-year. Low-level resistance to ganciclovir occurs through mutations in the CMV UL97 (phosphotransferase) gene, and high-level resistance to ganciclovir typically occurs because of mutations in both the CMV UL97 and UL54 (DNA polymerase) genes (*699–704*). Resistance to foscarnet or cidofovir each occurs because of mutations in the CMV UL54 gene. High-level resistance to ganciclovir is frequently associated with cross resistance to cidofovir (*701*) and occasionally to foscarnet (*703*).

Although early relapse is typically not a result of resistance, later relapse often is. Because patients with resistant CMV nearly always have mutations in the CMV UL97 gene, and because a limited number of mutations are responsible for most drug resistance, susceptibility testing in peripheral blood using a CMV DNA PCR assay and sequencing for CMV UL97 mutations or using a point mutation assay (*705,706*) might be reasonable for patients who relapse on therapy (*707*). Virus in the eye and in the blood are identical in >90% of cases (*708*), so evaluating the blood for resistance is reasonable, and the detection of resistance in the blood or urine correlates with clinical behavior of the retinitis (*709*). Sequencing the UL97 gene from PCR-amplified specimens from blood can be accomplished in <48 hours, correlates well with conventional drug susceptibility testing and clinical outcomes (*707*), and, therefore, has clinical utility **(BII)** when conventional methods of culture and susceptibility testing and viral sequencing are not available or are too time consuming or costly. Conversely, CMV viral load measurements are of limited utility clinically because of their poor positive predictive value, but do have reasonable negative predictive value and might have utility in excluding resistance when sequencing is not available **(BII).** UL97 mutants usually respond to foscarnet, as do most UL54 mutants (except those associated with resistance to foscarnet).

Patients with low-level ganciclovir-resistant isolates in the eye might respond to a ganciclovir implant because of the higher local levels of ganciclovir resulting from this form of therapy. However, patients with high-level ganciclovir-resistant isolates typically will not respond and will require a switch to alternative therapy.

Preventing Recurrence

After induction therapy, secondary prophylaxis (i.e., chronic maintenance therapy) is recommended for life **(AI)** (*664,668,673,674,710*), unless immune reconstitution occurs as a result of ART. Regimens demonstrated to be effective for chronic suppression in randomized, controlled clinical trials include parenteral ganciclovir or valganciclovir, parenteral foscarnet, combined parenteral ganciclovir and foscarnet, parenteral cidofovir, and (for retinitis only) ganciclovir administration through intraocular implant **(AI).** Repetitive intravitreous injections of fomivirsen also have been demonstrated to be effective in randomized clinical trials, but this drug is no longer available in the United States.

Repetitive intravitreous injections of ganciclovir, foscarnet, and cidofovir have been effective for secondary prophylaxis of CMV retinitis in uncontrolled case series. Because of the risk for hypotony and uveitis, the intravitreal administration of cidofovir should be reserved for extraordinary cases. Intraocular therapy alone does not provide protection to the contralateral eye or to other organ systems and typically should be combined with oral valganciclovir.

The choice of a chronic maintenance regimen for patients treated for CMV disease should be made in consultation with a specialist. For patients with retinitis, this decision should be made in consultation with an ophthalmologist and should consider the anatomic location of the retinal lesion, vision in the contralateral eye, the immunologic and virologic status of the patient, and the patient's response to ART.

Patients with lesions that immediately threaten vision need prompt anti-CMV therapy because progression of the retinitis can occur during the time in which immune recovery is occurring (*674,675*). Patients with retinitis that immediately threatens sight still might benefit most from the use of the ganciclovir implant because of its ability to deliver high concentrations of drug locally and its superior ability to control retinitis progression **(BI).** However, replacement of the ganciclovir implant at 6–8 months might not be necessary for those with sustained immune recovery. If the ganciclovir implant is used, it should be combined with oral valganciclovir until immune recovery occurs **(BIII).**

Chronic maintenance therapy is not routinely recommended for gastrointestinal disease but should be considered if relapses occur **(BII).** A role for maintenance therapy for CMV pneumonitis has not been established **(CIII).**

Discontinuing Secondary Prophylaxis (Chronic Maintenance Therapy)

Multiple case series have reported that maintenance therapy can be discontinued safely among adult and adolescent patients with CMV retinitis whose CD4+ counts have indicated a sustained (e.g., 3–6 months) increase to >100 cells/μL in response to ART (*711-716*). Such patients have remained disease free for >30–95 weeks in clinical trials and case series, whereas during the pre-ART era, retinitis typically reactivated in <6–8 weeks after stopping CMV therapy. Plasma HIV RNA levels were varied among these patients, demonstrating that the CD4+ count is the primary determinant of immune recovery to CMV. Discontinuing secondary prophylaxis (chronic maintenance therapy) is reasonable for patients with a sustained (3–6 months) increase in CD4+ counts >100 cells/μL in response to ART **(BII)** (*711–715,717,718*). Such decisions should be made in consultation with an ophthalmologist and should include magnitude and duration of CD4+ count increase, anatomic location of the retinal lesions, vision in the contralateral eye, and the feasibility of regular ophthalmologic monitoring **(BII).** The relapse rate among patients whose anti-CMV therapy has been discontinued for immune recovery is 0.03 per person-year (i.e., 3% per year) and no level of CD4+ count is absolutely safe (relapses have been reported at CD4+ counts of 1,250 cells/μL). Therefore, all patients who have had anti-CMV maintenance therapy discontinued should continue to undergo regular ophthalmologic monitoring for early detection of CMV relapse and for IRU, optimally every 3 months (**AII**). Monitoring CMV viral load has poor positive predictive value for relapse of the retinitis and, therefore, is not recommended **(DII).**

Relapse of CMV retinitis occurs frequently among patients whose anti-CMV maintenance therapies have been discontinued and whose CD4+ counts have decreased to <50 cells/μL (*717*). Therefore, reinstitution of secondary prophylaxis should occur when the CD4+ count has decreased to <100 cells/μL **(AIII).**

Special Considerations During Pregnancy

The diagnostic considerations among pregnant women are the same as for nonpregnant women. Indications for treatment of CMV infection during pregnancy are the same as for nonpregnant HIV-infected adults **(AIII).** For retinal disease, use of intraocular implants or intravitreous injections for local therapy should be considered in the first trimester, if possible, to limit fetal exposure to systemically administered antiviral drugs **(CIII).** Systemic antiviral therapy as discussed should then be started after the first trimester.

Ganciclovir is embryotoxic among rabbits and mice and teratogenic (i.e., cleft palate, anophthalmia, aplastic kidney and pancreas, and hydrocephalus) in rabbits (*719–721*). Safe use in human pregnancy after organ transplantation has been reported (*719,720*), and use in late pregnancy to treat fetal CMV infection in HIV-uninfected women has also been reported (*722*). Foscarnet is associated with an increase in skeletal anomalies or variants in rats and rabbits. No experience with use early in human pregnancy has been reported. A single case report of use in the third trimester described normal infant outcome (*723*). Cidofovir is embryotoxic and teratogenic (i.e., meningomyelocele and skeletal abnormalities) among rats and rabbits. No experience with use of cidofovir in human pregnancy has been reported; use in pregnancy is not recommended **(DIII).**

On the basis of limited data, toxicity reports and studies, and ease of use of the various drugs, valganciclovir is recognized as the treatment of choice during pregnancy **(BIII).** No experience has been reported with the use of valganciclovir in human pregnancy, but concerns are expected to be the same as with ganciclovir. The fetus should be monitored by fetal-movement counting in the third trimester and by periodic ultrasound monitoring after 20 weeks of gestation to look for evidence of hydrops fetalis indicating substantial anemia. Because toxicity of foscarnet is primarily renal, weekly monitoring of amniotic fluid volumes by ultrasound is recommended after 20 weeks of gestation to detect oligohydramnios if foscarnet is used.

Rarely, ultrasound findings in the fetus (e.g., cerebral calcifications, abdominal and liver calcifications, hydrops, microcephaly, ventriculomegaly, ascites, and echogenic fetal bowel) might indicate the possibility of in utero CMV infection among pregnant women with CMV end-organ disease (*724*). In this case, consideration of invasive testing (i.e., amniocentesis and fetal umbilical blood sampling) must be individualized on the basis of clinical history and serologic findings, gestational age, potential risk for HIV transmission, and maternal preference (*725*). Referral to a maternal-fetal medicine specialist for evaluation, counseling, and potential further testing is recommended.

On the basis of data in HIV-uninfected women, transmission of CMV from mother to infant might occur in utero. However, symptomatic infection in the newborn is usually related to primary CMV infection in the mother during pregnancy, and because >90% of HIV-infected pregnant women are CMV antibody positive in the majority of studies, the risk for symptomatic infection in the fetus is low (*726–730*). Therefore, treatment of asymptomatic maternal CMV infection during pregnancy solely to prevent infant infection is not indicated **(DIII).**

Herpes Simplex Virus Disease

Epidemiology

Infections with human herpes simplex virus type 1 (HSV-1) and type 2 (HSV-2) are common, with a seroprevalence of HSV-1 among adults of approximately 60% and a seroprevalence of HSV-2 among persons aged ≥12 years in the United States of 17% (731). Approximately 70% of HIV-infected persons are HSV-2 seropositive and 95% are seropositive for either HSV-1 or HSV-2 (732). In most HSV-infected persons, HSV infections are unrecognized clinically. However, regardless of the clinical severity of infection, reactivation on mucosal surfaces occurs intermittently and can result in transmission. HSV-2 is a risk factor for HIV acquisition, and HSV-2 reactivation results in increases in HIV RNA levels in coinfected patients.

Clinical Manifestations

Orolabial herpes is the most common manifestation of HSV-1 infection. Classic manifestations include a sensory prodrome in the affected area, rapidly followed by the evolution of lesions from papule to vesicle, ulcer, and crust stages on the lips. The course of illness in untreated subjects is 7–10 days. Lesions recur 1–12 times per year and can be triggered by sunlight or physiologic stress.

Genital herpes is the most common manifestation of HSV-2 infection. Genital mucosal or skin lesions are similar to external orolabial lesions in appearance and evolution. Local symptoms might include a sensory prodrome consisting of pain and pruritis. Ulcerative lesions are usually the only stage observed on mucosal surfaces. Mucosal disease is occasionally accompanied by dysuria or vaginal or urethral discharge; inguinal lymphadenopathy, particularly in primary infection, is common with genital herpes *(733)*. These classic manifestations occur in certain patients, but most persons with genital herpes have mild and atypical lesions that are not brought to medical attention and that cannot be diagnosed by physical examination. In profoundly immunocompromised patients, extensive, deep, nonhealing ulcerations might occur. These lesions have been reported most often in those with $CD4^+$ counts of <100 cells/μL and also might be more commonly associated with acyclovir-resistant virus (*734*).

The episodes of genital HSV-1 infection are indistinguishable from genital HSV-2 infection but genital HSV-1 infection recurs less frequently than genital HSV-2 infection.

Nonmucosal HSV infections, such as HSV keratitis, HSV encephalitis, HSV hepatitis, and herpetic whitlow, are similar in presentation to those manifestations observed in HIV-seronegative persons; disseminated HSV infection is rare. HSV retinitis manifests as acute retinal necrosis (ARN) and can lead rapidly to loss of vision.

Diagnosis

Because mucosal HSV infections cannot be diagnosed accurately without laboratory confirmation, especially in HIV-seropositive patients, a laboratory diagnosis should be pursued in all cases (*529*). Viral culture, HSV DNA PCR, and HSV antigen detection are available methods for diagnosis of mucocutaneous HSV lesions caused by HSV. PCR is the most sensitive method, but is not widely available. The virus detected in genital lesions should be typed, because HSV-1 recurs less frequently than HSV-2 in the genital area. Type-specific serologic assays are commercially available and can be used in asymptomatic persons or those with atypical lesions. Because of the poor sensitivity and specificity of clinical diagnosis, extensive interactions between HIV and HSV-2, and the availability of effective therapy for HSV-2, routine type-specific serologic testing for HSV-2 should be considered in persons who seek HIV care. Diagnosis of HSV-2 should be accompanied by counseling that discusses the risk for transmission of infection to sex partners. Guidelines for counseling are provided in the 2006 CDC STD treatment guidelines (http://www.cdc.gov/std/treatment).

Preventing Exposure

The majority of HIV-infected persons have HSV-1 and -2 infections. However, prevention of acquisition of HSV is important for those who are uninfected. HSV-2-seronegative HIV-infected persons should ask their partners to be tested using type-specific serology before initiating sexual activity, because disclosure of HSV-2 in heterosexual HSV-2-discordant couples was associated with reduced risk for transmission of HSV-2 **(BII)** (*735*). Consistent use of latex condoms reduced HSV-2 acquisition from women to men and from men to women, and their use should be encouraged for prevention of transmission of HSV-2 and other sexually transmitted pathogens **(AII)** (*736*). HIV-infected persons should specifically avoid sexual contact when their partners have overt (genital or orolabial) herpetic lesions **(AII).** However, sexual transmission of HSV can occur during asymptomatic shedding. The use of suppressive antiviral therapy (valacyclovir 500 mg once daily) in persons with genital herpes reduced HSV-2 transmission to susceptible heterosexual partners by 50% (*737*); the effectiveness of this approach in reducing HSV-2 transmission from HIV-seropositive persons or to HIV-seropositive persons has not been evaluated.

Preventing Disease

The dose, duration, and efficacy of antiviral prophylaxis after exposure to HSV have not been evaluated.

Treatment of Disease

Patients with HSV infections can be treated with episodic therapy when lesions occur or with daily therapy to prevent recurrences. The management of genital HSV-2 in HIV-infected persons should include several factors, including frequency and severity of HSV recurrences, the risk for HSV-2 transmission to susceptible partners, and the potential for interactions between HIV and HSV-2 that might result in increased HIV in plasma and genital secretions. Treatment for individual recurrences does not influence the natural history of genital HSV-2 infection and does not reduce the risk for HSV-2 transmission to sex partners, a major concern of persons with genital herpes.

Patients with orolabial lesions can be treated with oral valacyclovir, famciclovir, or acyclovir for 5–10 days **(AII).** Severe mucocutaneous HSV lesions respond best to initial treatment with IV acyclovir **(AII)** (*734,738*). Patients may be switched to oral therapy after the lesions have begun to regress. Therapy should be continued until the lesions have completely healed. Genital HSV infection should be treated with oral valacyclovir, famciclovir, or acyclovir for 5–14 days **(AI).** Short-course therapy (1, 2, or 3 days) should not be used in patients with HIV infection.

Monitoring and Adverse Events, Including Immune Reconstitution Inflammatory Syndrome (IRIS)

Acyclovir, valacyclovir, and famciclovir are occasionally associated with nausea or headache. No laboratory monitoring is needed in patients receiving episodic or suppressive therapy unless the patient has substantial renal impairment. For patients receiving high-dose IV acyclovir, monitoring of renal function and dose adjustment as necessary are recommended at initiation of treatment and once or twice weekly for the duration of treatment. Thrombotic thrombocytopenic purpura/hemolytic uremic syndrome has been reported among HIV-infected patients treated with high-dose (8 grams/day) valacyclovir but has not been reported at doses used for therapy of HSV infection (*742*).

Cutaneous lesions that are atypical and occasionally recalcitrant to therapy have been reported in persons initiating ART and have been attributed to IRIS

Management of Treatment Failure

Treatment failure related to resistance to anti-HSV drugs should be suspected if lesions do not begin to resolve within 7–10 days after initiation of therapy. Among immunocompromised patients with suspected acyclovir-resistant HSV, viral culture of the lesion should be obtained and, if virus is isolated, susceptibility testing performed to confirm drug resistance **(AII)** (*743*).

The treatment of choice for acyclovir-resistant HSV is IV foscarnet **(AI)** (*744,745*). Topical trifluridine, cidofovir, and imiquimod also have been used successfully for lesions on external surfaces, although prolonged application for 21–28 days or longer might be required **(CIII).**

Preventing Recurrence

Most recurrences of genital herpes can be prevented using daily anti-HSV therapy, and this is recommended for persons who have frequent or severe recurrences **(AI)** (*739*). The option for suppressive therapy should be discussed with every HSV-2-infected patient. Suppressive therapy with oral acyclovir, valacyclovir, or famciclovir is effective in preventing recurrences **(AI)** (*739–741*). Suppressive therapy with valacyclovir should be 500 mg twice daily in HIV-infected persons **(AI),** or twice-daily regimens with acyclovir or famciclovir should be used. Daily anti-HSV suppressive therapy in HIV-infected persons also results in a decrease in HIV concentration in plasma and anal and genital secretions. Whether this regimen results in clinical benefit or decreased infectiousness is not known.

HIV-infected patients receiving ART who have immune reconstitution often experience improvement in the frequency and severity of their clinical episodes of genital herpes. However, immune reconstitution does not reduce the frequency of genital HSV shedding.

Special Considerations During Pregnancy

Diagnosis of mucocutaneous HSV infections is the same for pregnant women as for nonpregnant women. Episodic therapy for first-episode HSV disease and for recurrences can be offered during pregnancy, but suppressive therapy is not used routinely. Visceral disease is more likely to occur during pregnancy and can be fatal. Acyclovir is the antiviral drug with the most reported experience in pregnancy and appears to be safe (*746*); therefore, acyclovir is the first choice for therapy of HSV infections in pregnancy **(AIII).**

An additional concern with HSV during pregnancy is the potential for HSV transmission to the fetus and neonate. The rate of HSV transmission to the newborn in HSV-2-seropositive pregnant women is low, unless the pregnant woman has acquired genital HSV in late pregnancy. The predominant risk for HSV transmission is maternal genital shedding of HSV at delivery. Cesarean delivery is recommended for women with a genital herpes prodrome or visible HSV genital lesions at the onset of labor **(BII)** (*724*). Maternal genital herpes is a risk factor for perinatal mother-to-child

HIV transmission (*747*). Whether HSV suppression reduces the risk for HIV transmission during pregnancy, birth, or breastfeeding is unknown.

Use of acyclovir in late pregnancy suppresses genital herpes outbreaks and reduces the need for Cesarean delivery for recurrent HSV in HIV-seronegative women (*748*) and is likely to have similar efficacy in HIV-seropositive women **(BII).** However, the use of acyclovir in HIV-infected pregnant women to reduce the risk for intrapartum HIV and HSV transmission to the neonate has not been evaluated.

HHV-6 and HHV-7 Disease

Epidemiology

The highest geometric mean titers of HHV-6 antibody occur during the first 3 years of life, indicating a clustering of primary infections in infants and toddlers (*749,750*). Approximately 90% of healthy children become infected with HHV-6 by 12 months of life (*751*), and virtually 100% acquire infection by 3 years of age (*750*). HHV-6 seroprevalence remains high throughout adulthood (*750,751*). Most children likely acquire infection through contact with the secretions of adult caretakers who shed the virus in saliva; approximately 85% of healthy or HIV-infected adults shed HHV-6 intermittently in their saliva (*752*).

Primary HHV-7 infection also usually occurs during early childhood. Most adults have serologic evidence of previous HHV-7 infection. (*753*). Eighty to ninety percent of HHV-7–infected adults, regardless of HIV status, shed HHV-7 intermittently in their saliva.

Clinical Manifestations

HHV-6B causes exanthem subitum (roseola), a common disease of childhood (*754*). In addition, HHV-6B is a major cause of emergency room visits and hospitalizations for infants and young children (*755*). HHV-6 also produces a spectrum of neurologic diseases, including encephalitis and febrile seizure (*756*). Although HHV-6 has been described as a cause of disease in other immunocompromised patients, it has not been identified as an important opportunistic pathogen in HIV-infected patients.

Both HHV-6 and HIV can simultaneously infect the same $CD4^+$ cells under experimental conditions. Studies evaluating the effect of HHV-6 coinfection on active HIV viral replication in vitro have yielded contradictory results, with some investigations documenting enhanced HIV replication (*757*), whereas others reported inhibition of HIV replication (*758*). In vivo studies have suggested a possible role for HHV-6 coinfection in the progression of HIV disease (*759,760*), but this remains unconfirmed.

HHV-7 has not been definitively documented to cause a specific disease, with no apparent correlation between HHV-7 and HIV plasma load, suggesting that HHV-7 infection might not be stimulated by or interact with HIV infection (*761*).

Diagnosis

A fourfold or greater rise in anti-HHV-6 antibody titer between acute and convalescent serum samples suggests that active viral replication has occurred. Detection of HHV-6 IgM in infants and young children is a reliable marker of primary infection, although extrapolation to adults is problematic because IgM can be detected during HHV-6 reactivation. Detection of HHV-6 DNA in cell-free plasma specimens by PCR suggests active HHV-6 replication (*762*).

Preventing Exposure

HHV-6 and HHV-7 are ubiquitous universal infections, and prevention of exposure is not feasible.

Preventing Disease

Because of the ubiquity of HHV-6 and -7 during early childhood and the lack of an effective vaccine, prevention of primary HHV-6 and -7 infections or HHV-6 disease is not feasible.

Treatment of Disease

Antiviral susceptibility patterns of HHV-6 resemble those of CMV. HHV-6 replication is readily inhibited by foscarnet, cidofovir, and ganciclovir at levels that are easily achievable in the human plasma. Indications for treatment of HHV-6 infection in HIV-seropositive patients are unclear. However, if disease in an HIV-infected person is determined to be caused by HHV-6, ganciclovir or foscarnet can be considered treatment options using treatment schedules and doses similar to those used for CMV disease **(CIII).** HHV-7 has not been recognized as a cause of disease in HIV-infected persons, and no recommendation for treatment can be made.

Monitoring and Adverse Events, Including Immune Reconstitution Inflammatory Syndrome (IRIS)

See CMV treatment recommendations for monitoring and adverse events. HHV-6 and -7 have not been demonstrated to be associated with IRIS.

Management of Treatment Failure

Mutations conferring resistance of HHV-6 to ganciclovir, cidofovir, and foscarnet have been described (*763*). Theoretically, treatment failures could be managed by switching classes of antiviral medications (e.g., changing from ganciclovir to foscarnet), but data are completely lacking **(CIII).**

Preventing Recurrence

No data exist on prevention of HHV-6 or HHV-7 reactivation from latency in HIV-infected patients. Use of antiviral medications for this indication is not recommended **(DIII).**

Special Considerations During Pregnancy

Given the epidemiology of HHV-6 infection, symptomatic infection and indications for treatment in pregnancy are expected to be rare. See special considerations for CMV for a discussion of concerns regarding use of ganciclovir and foscarnet in pregnancy. Treatment of HHV-7 during pregnancy is not indicated.

Varicella-Zoster Virus Diseases

Epidemiology

Approximately 95% of adults (aged ≥21 years) born in the United States have had primary varicella-zoster virus (VZV) infection, known as varicella (or chickenpox). Reactivation of latent VZV results in herpes zoster (or shingles). A person's lifetime risk for herpes zoster is 15%–20%, with the highest incidence occurring in the elderly and immunocompromised persons. The incidence of herpes zoster is >15-fold higher for HIV-infected adults than for age-matched controls (*764*). Herpes zoster can occur in HIV-infected adults at any $CD4^+$ count, but frequency of disease is highest with $CD4^+$ counts of <200 cells/μL and is not reduced by ART (*765–767*).

Clinical Manifestations

The varicella rash first appears on the head, then on the trunk, and finally on the extremities, evolving through stages of vesicles, pustules, and crusts. The rash is characterized by rapid evolution of lesions during the initial 8–12 hours and by successive crops of new lesions. New vesicle formation continues for 2–4 days, accompanied by pruritus, fever, headache, malaise, and anorexia. Varicella can cause substantial morbidity in HIV-seropositive adolescents and adults. Visceral dissemination, especially VZV pneumonitis, is well documented (*768*). Because most HIV-infected adults in the United States are VZV seropositive, varicella is an uncommon occurrence in this population.

Herpes zoster manifests as a painful cutaneous eruption in a dermatomal distribution, often preceded by prodromal pain. The most common sites for herpes zoster are the thoracic dermatomes (40%–50% of cases), followed by cranial nerve (20%–25%), cervical (15%–20%), lumbar (15%), and sacral (5%) dermatomes. Skin changes begin with an erythematous maculopapular rash, followed by the appearance of clear vesicles and accompanied by pain (which might be severe). New vesicle formation typically continues for 3–5 days, followed by lesion pustulation and scabbing. Crusts typically persist for 2–3 weeks and cutaneous dissemination might be as high as 25% to 50%. About 20%–30% of HIV-infected patients have one or more subsequent episodes of herpes zoster, which might involve the same or different dermatomes. The probability of a recurrence of herpes zoster within 1 year of the index episode is approximately 10% (*767,769*). Approximately 10%–15% of HIV-seropositive patients report post-herpetic neuralgia (PHN) as a complication following herpes zoster (*767,770*).

Most herpes zoster-related complications, including herpes zoster dissemination, occur in patients with $CD4^+$ counts of <200 cells/μL (*771*). The CNS is the primary target organ for herpes zoster dissemination in patients coinfected with HIV. Various VZV-related neurologic syndromes occur in HIV-infected patients, including CNS vasculitis, multifocal leukoencephalitis, ventriculitis, myelitis and myeloradiculitis, optic neuritis, cranial nerve palsies and focal brain-stem lesions, and aseptic meningitis.

ARN and progressive outer retinal necrosis (PORN) are variants of necrotizing retinopathy caused by VZV. Although ARN can occur in both immunocompetent and immunocompromised patients, PORN occurs almost exclusively in AIDS patients with $CD4^+$ count <100 cells/μL (*772*). In contrast to ARN, PORN is characterized by minimal inflammation in the aqueous and vitreous humor, absence of retinal vasculitis, and multiple discrete peripheral lesions in the outer retinal layer (*773*). PORN lesions rapidly coalesce, causing full-thickness retinal necrosis and subsequent retinal detachment (*774*). Both ARN and PORN are associated with high rates of visual loss.

Diagnosis

Varicella and herpes zoster are distinctive in appearance and can usually be diagnosed clinically. Varicella can be diagnosed retrospectively by documenting seroconversion. When lesions are atypical or the diagnosis is uncertain, swabs from a fresh lesion or tissue biopsies can be submitted for viral culture, direct fluorescent antigen testing, or PCR. Histopathology and PCR can aid with diagnosis of VZV infections of visceral organs (e.g., encephalitis, retinitis, and pneumonitis).

Preventing Exposure

HIV-infected persons who are susceptible to VZV (i.e., those who have not been vaccinated, have no history of varicella or herpes zoster, or are seronegative for VZV) should avoid exposure to persons with chickenpox or herpes zoster **(AII)**. VZV-susceptible household contacts of susceptible HIV-infected persons should be vaccinated to prevent acquisition of chickenpox and potential transmission of VZV to their susceptible HIV-infected contacts **(BIII).**

Preventing Disease

Postexposure Prophylaxis

For prophylaxis against chickenpox, HIV-infected children and adults who are susceptible to VZV should receive varicella-zoster immune globulin (VariZIG™) as soon as possible (but within 96 hours) after close contact with a person who has active varicella or herpes zoster **(AIII)**. As of June 2007, VariZIG can be obtained only under a treatment IND; contact FFF Enterprises, 800-843-7477. The duration of protection should last at least for 3 weeks. Patients receiving monthly high-dose immune globulin intravenous (IGIV) (>400 mg/kg) are likely to be protected and probably do not require VariZIG if the last dose of IGIV was administered <3 weeks before exposure. Risk for VZV transmission is higher from exposure to a patient with chickenpox than from exposure to localized herpes zoster.

Among VZV-susceptible immunocompetent children, postexposure varicella vaccination has been shown to reduce the risk for chickenpox developing in children and is more effective than pre-emptive therapy with acyclovir. Post-exposure varicella vaccination (for patients with $CD4^+$ counts of >200 cells/μL) or short-term post-exposure administration of acyclovir may be considered for preventing chickenpox among susceptible HIV-infected adolescents or adults, but has not been studied in this population **(CIII)**.

Long-term–drug prophylaxis for prevention of primary VZV infection in HIV-infected persons is not recommended **(DIII).**

Vaccination

The live attenuated varicella vaccine has been documented to be safe and immunogenic in HIV-infected children aged ≥8 years with $CD4^+$ counts ≥200 cells/μL ($CD4^+$ percentage is ≥15%) (*775*) and is recommended for those children (776). No studies have evaluated the vaccine in HIV-infected adolescents or adults, but varicella vaccination (two doses, administered 3 months apart) may be considered in HIV-seropositive/VZV-seronegative persons ≥8 years old with $CD4^+$ counts ≥200 cells/μL (**CIII**). If vaccination results in disease because of vaccine virus, therapy with acyclovir is recommended (**AIII**). Administration of varicella vaccine to more severely immunocompromised HIV-infected patients is not recommended (**DIII**). Because of the high prevalence of VZV seropositivity in adults, use of varicella vaccine in this population will be infrequent. Routine serologic testing to determine the VZV serologic status of HIV-infected adults is not recommended.

Treatment of Disease

No controlled prospective studies of antiviral therapy for chickenpox in HIV-infected adults have been reported. For uncomplicated varicella, recommended treatment options are oral acyclovir (20 mg/kg body weight up to a maximum dose of 800 mg five times daily), valacyclovir (1 g PO tid), or famciclovir (500 mg PO tid) for 5–7 days **(AII).** IV acyclovir for 7–10 days is the recommended initial treatment for HIV-infected patients with severe chickenpox **(AIII)** (*768,777,778*). If no evidence of visceral involvement with VZV is available, switching to oral antiviral therapy after the patient has defervesced may be permissible **(AIII)** (*779*).

Prompt antiviral therapy should be instituted in all immunosuppressed herpes zoster patients within 1 week of rash onset or any time before full crusting of lesions. The recommended treatment options for acute localized dermatomal herpes zoster in HIV-infected patients are oral valacyclovir, famciclovir, or acyclovir for 7–10 days **(AII),** although longer durations of therapy should be considered if lesions resolve slowly. Valacyclovir or famciclovir are preferred because of their improved pharmacokinetic properties and simplified dosing schedule. If cutaneous lesions are extensive or if visceral involvement is suspected, IV acyclovir should be initiated and continued until clinical improvement is evident **(AII)** (*780*). A switch from IV acyclovir to oral antiviral therapy (to complete a 10–14 day treatment course) is reasonable when formation of new cutaneous lesions has ceased and the signs and symptoms of visceral VZV infection are improving **(AIII)**. Because of the absence of data to support benefit in this population, adjunctive corticosteroid therapy for herpes zoster is not recommended (**DIII**).

Optimal antiviral therapy for PORN remains undefined (*774,781*). Prognosis for visual preservation in involved eyes is poor despite aggressive antiviral therapy. A treatment regimen recommended by certain specialists is a combination of IV ganciclovir and foscarnet, plus intravitreal injections of ganciclovir and/or foscarnet **(AIII).** Optimization of ART in HIV-infected patients with PORN is also recommended **(AIII).** Anecdotal reports have described success with IV cidofovir. ARN appears to be more responsive to antiviral therapy; one recommended treatment is high-dose IV acyclovir (10 mg/kg every 8 hours for 10–14 days), followed by prolonged oral valacyclovir (1 gram tid for 6 weeks) **(AIII).** Involvement of an experienced ophthalmologist in management of patients with VZV retinitis is strongly recommended **(AIII).**

The incidence of herpes zoster in HIV-infected adults does not appear to be affected by ART therapy. Optimization of ART is recommended in patients with VZV infections (e.g., PORN) **(AIII)** that are difficult to treat.

Monitoring and Adverse Events, Including Immune Reconstitution Inflammatory Syndrome (IRIS)

For monitoring and adverse event recommendations related to anti-herpesvirus drugs, see preceding sections on HSV and CMV. Providers should be aware of the increased incidence of herpes zoster after initiation of ART. Such episodes should be treated as other episodes of herpes zoster.

Immune reconstitution following initiation of ART might be associated with an increased frequenty of VZV reactivation (*782*,*783*). Between 4 and 16 weeks after beginning ART, the risk for herpes zoster increases two- to fourfold from baseline. During the 6 months after the start of combination ART, the incidence of herpes zoster exceeds 90 episodes per 1,000 person years. The percentage of $CD8^+$ lymphocytes at baseline and the magnitude of their increase at 1 month after initiation of drug therapy are strongly associated with an increased risk for herpes zoster. The clinical presentation and natural history of herpes zoster in the setting of immune reconstitution do not differ from those observed in other HIV-infected patients.

Management of Treatment Failure

Treatment failure caused by resistance of VZV to acyclovir (and related drugs) should be suspected if lesions do not improve within 10 days of initiation of therapy or if they have an atypical (e.g., verrucous) appearance. A viral culture should be obtained, and if VZV is isolated, susceptibility testing performed to establish antiviral drug susceptibility or resistance and to document the need for alternative therapy. Among patients with suspected or proven acyclovir-resistant VZV infections, treatment with IV foscarnet is recommended **(AII)** (*784*).

Preventing Recurrence

No intervention has been recognized as preventing the recurrence of herpes zoster among HIV-infected persons. An attenuated virus vaccine for prevention of herpes zoster has been approved for use in immunocompetent persons aged ≥60 years, but data regarding its use in HIV-infected persons are lacking. Prospective clinical trials to evaluate the safety and immunogenicity of herpes zoster vaccine in HIV-seropositive subjects are planned. Administration of herpes zoster vaccine to HIV-infected persons is not recommended **(DIII)**.

Special Considerations During Pregnancy

HIV-infected pregnant women who are susceptible to VZV and have close contact to a person with active varicella or herpes zoster should receive VariZIG as soon as possible (within 96 hours) after exposure to VZV **(AIII).** If oral acyclovir is used for post-exposure prophylaxis, VZV serology should be performed so that the drug can be discontinued if the patient is seropositive for VZV **(CIII).** Pregnant women should not receive varicella vaccine **(EIII).**

Specific risks among HIV-infected women with varicella during pregnancy have not been reported. For HIV-seronegative women with chickenpox, the risk for transmitting VZV to the infant resulting in congenital varicella syndrome is 0.4% when infection occurs at or before 12 weeks of gestation, 2.2% with infection at 13–20 weeks, and is negligible after 20 weeks (*785*). Women with varicella during the first half of pregnancy should be counseled about the risks and offered detailed ultrasound surveillance for findings indicative of fetal congenital varicella syndrome (*785*). Administration of varicella-zoster immune globulin does not alter the risk for congenital varicella syndrome. Infants born to women who have chickenpox from 5 days before until 2 days after delivery should receive VariZIG to reduce the severity and mortality of neonatal varicella acquired during maternal viremia **(AIII)** (*783*)**.**

Oral acyclovir or valacyclovir are the preferred treatments for HIV-infected pregnant women who have uncomplicated chickenpox during pregnancy **(BIII).** Pregnant women who have severe varicella or who exhibit signs or symptoms of VZV pneumonitis should be hospitalized and treated with IV acyclovir (10 mg/kg every 8 hours) **(AII).**

No controlled studies of antiviral therapy of herpes zoster during pregnancy have been reported. Recommended therapy for uncomplicated shingles in pregnant HIV-infected women is oral acyclovir or valacyclovir **(BIII).**

Human Herpesvirus-8 Disease

Epidemiology

Human herpesvirus-8 (HHV-8) seroprevalence among the general population in the United States is 1%–5%. The seroprevalence is greater among MSM (20%–77%) (*800*), regardless of HIV infection, and is also higher in certain Mediterranean countries (10%–20%) and in parts of sub-Saharan Africa (30%–80%). HHV-8 is associated with all forms of KS (i.e., classic, endemic, transplant-related, and AIDS-related) and certain rare neoplastic (e.g., primary effusion lymphoma [PEL]) and lymphoproliferative disorders (multicentric Castleman disease [MCD]). The precise pathogenesis is unclear even though seroconversion to HHV-8 precedes the development of these tumors (*786*). Patients who are HHV-8 seropositive and have HHV-8 viremia have an increased risk (approximately ninefold) for experiencing KS compared with HHV-8 seropositive men without HHV-8 viremia (*787*), and HHV-8 viremia almost always accompanies symptomatic episodes of MCD (*788*).

The overall incidence of KS was as high as 20% among patients with AIDS before the advent of effective ART.

However, even before the widespread use of ART, the incidence had declined, perhaps because of ganciclovir, foscarnet, and cidofovir use for treatment of CMV disease. These agents inhibit the replication of HHV-8 in vitro, (*789,790, 803*) and observational studies indicate that patients receiving ganciclovir or foscarnet (but not acyclovir) develop KS at a reduced rate (*710,791–793*). The incidence of KS has declined after the introduction of PIs and HAART (*794*). PEL and MCD remain rare (*795*).

KS and PEL are described most frequently among HIV-infected persons with more advanced immunosuppression ($CD4^+$ counts of <200 cells/μL), although they can occur at any $CD4^+$ count. Episodes of MCD might present at any $CD4^+$ count.

Clinical Manifestations

Most persons with chronic HHV-8 infection are asymptomatic (*796*). Acquisition of HHV-8 has been associated with a primary infection syndrome consisting of fever, rash, lymphadenopathy, bone marrow failure, and occasional rapid progression to KS (*797,798*). MCD manifests with generalized adenopathy and fever and can progress to multi-organ failure (*795*). KS symptoms vary widely, but most persons have nontender, purplish, indurated skin lesions. Intraoral lesions are common and visceral dissemination can occur, occasionally without the presence of skin lesions. Other manifestations of HHV-8 infection are beyond the scope of this report. Asymptomatic HHV-8 infection is often associated with HHV-8 shedding in the saliva and occasional shedding in genital secretions (*796,799,800*); viral shedding might result in HHV-8 transmission to uninfected partners.

Diagnosis

Routine screening for HHV-8 by PCR or serologic testing for HHV-8 antibody is not indicated for HIV-infected persons. Use of PCR to quantify HHV-8 in the peripheral blood is helpful in the diagnosis and management of persons with MCD (*788*).

Preventing Exposure

Recommendations related to preventing exposure to HHV-8 do not exist.

Preventing Disease

Despite observational evidence supporting a role for anti-HHV-8 therapy in preventing the development of KS, the toxicity of current anti-HHV-8 therapy outweighs the potential benefits of administration **(DIII).**

Treatment of Disease

Although ganciclovir, foscarnet, and cidofovir have in vitro activity against HHV-8, and limited studies indicate these agents might be associated with reduced KS disease progression or lesion regression, larger and more definitive studies are needed to determine whether antiviral therapy has a useful role in managing HHV-8-associated diseases. KS regression has been documented after ganciclovir or foscarnet therapy (*801–803*), although one study indicated cidofovir was ineffective (*804*). The use of IV ganciclovir or oral valganciclovir is, however, recommended in the treatment of MCD **(BII)** (*805*) and might be useful adjunctive therapy in the treatment of PEL **(BII)** (*806,807*). Highly active ART that suppresses HIV replication should be administered to all HIV-infected persons with KS, PEL, or MCD **(BII)**, although insufficient evidence exists to support using one HAART regimen over another. Chemotherapy, in combination with ART, should be considered for patients with PEL or visceral KS **(BII)** and might be a useful adjunctive therapy in persons with widely disseminated cutaneous KS (**CIII**). Rituximab also appears to be an effective alternative to antiviral therapy in the treatment of MCD **(BII)** (*808*).

Monitoring and Adverse Events, Including Immune Reconstitution Inflammatory Syndrome (IRIS)

Fatal IRIS has been reported in persons initiating ART with pre-existing KS and MCD. The frequency of HHV-8-associated IRIS is not known but suppression of HIV replication and immune reconstitution are key components of therapy and initiation of ART should not be delayed.

Preventing Recurrence

Effective suppression of HIV replication with ART among HIV-infected patients with KS might prevent KS progression or occurrence of new lesions and should be considered for all persons with evidence of active KS **(BII).** Suppression of HIV replication also is recommended for persons with MCD **(BII)** and those with malignant lymphoproliferative disorders.

Special Considerations During Pregnancy

The seroprevalence of HHV-8 infection among HIV-infected pregnant women varies by geographic area, ranging from 1.7% among U.S.-born and 3.6% among Haitian-born women in New York City to 11.6% among pregnant women from four other U.S. cities (*809*). Pregnancy does not appear to affect the prevalence of antibodies to HHV-8 or the antibody levels (*84*), although levels of HHV-8 DNA in the peripheral blood might increase late in pregnancy (*810*). HHV-8 seropositivity does not appear to influence pregnancy outcome. Routine screening for HHV-8 by PCR or serology is not indicated for

HIV-infected pregnant women **(DII).** In vitro models suggest that beta-human chorionic gonadotropin induces regression of KS tumors, but clinical reports on the incidence and natural history of KS in pregnancy are conflicting (*811–814*).

Diagnosis of KS or other HHV-8-associated neoplasms in pregnancy should be the same as in nonpregnant women. Recommendations for the treatment of HHV-8 malignancies are beyond the scope of these guidelines. Treatment should be undertaken in consultation with a specialist.

Perinatal transmission of HHV-8 might occur infrequently. Evidence supporting vertical transmission during pregnancy or the intrapartum period includes cases of KS occurring in the infant shortly after birth (*815,816*), higher risk for transmission with higher maternal antibody titer (and by inference higher maternal levels of HHV-8) (*817*), and detection of similar strains of HHV-8 DNA by PCR in specimens drawn at birth from HHV-8-seropositive mothers and their infants (*818*). Data indicate increased mortality through age 24 months among HIV-infected infants born to HHV-8-seropositive compared with HHV-8-seronegative mothers (*815–817,819–824*), but these studies could not completely account for other confounding factors affecting HIV-infected infants. The majority of studies document a substantially higher rate of HHV-8 seropositivity among children born to HHV-8 antibody-positive compared with HHV-8 antibody-negative women (*819–824*).

Human Papillomavirus Disease

Epidemiology

Human papillomavirus (HPV), a common sexually transmitted DNA virus (*825–830*), is the most frequent cause of cervical cancer (*831–833*). Most HPV infections, however, resolve or become latent and undetectable (*828,834,835*), whereas persistent infection with an oncogenic HPV type is required for tumorigenesis. Of more than 100 HPV types, more than 40 can infect the cervix, and at least 13 of these are considered oncogenic types, including HPV 16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, and 66 (*836*). HPV16 alone accounts for approximately 50% of cervical cancers in the general population and HPV18 for another 10%–15%, whereas the other oncogenic HPV types each individually account for <5% of tumors (*832,837*). HPV types 6 and 11 cause 90% of genital warts (*838*).

Cervical cancer is the second most common cause of cancer in women worldwide, with almost twofold higher incidence in developing countries than in industrialized countries (*839*). In the United States and Western Europe, women with HIV/AIDS have several-fold higher rates of cervical cancer compared with the general population, according to studies linking population-based cancer registries with registries for HIV/AIDS (*840–843*). In Africa, findings have varied (*844*), but the only African study with a prospective registry-based design reported substantially increased risk for cervical cancer in women with HIV/AIDS, and cervical cancer represented 10% of all tumors detected (*845*). Furthermore, HIV seropositivity is associated with a high prevalence of HPV infection, low-grade cervical intraepithelial neoplasia (CIN), and the precursor to cervical cancer, CIN 3 (*846–865*). Among HIV-infected women, rates of oncogenic HPV and high-grade CIN increase with diminished $CD4^+$ count and higher HIV RNA levels (*858,860,866–876*).

Other cancers caused by oncogenic HPV infection include most anal cancers and a subset of tumors of the vulva, vagina, penis, oral cavity, and oropharynx (*836,877*). HPV16 is the type present in the majority of these HPV-positive noncervical cancers. As with cervical cancer, the incidence of anal cancer and the other HPV-associated tumors is substantially higher in patients with HIV/AIDS than in the general population (*841,842,878*). Furthermore, high-grade anal intraepithelial neoplasia (AIN), the likely anal cancer precursor lesion, is more common in HIV-seropositive adults than in HIV-seronegative adults (*879–883*) as are anal and genital warts and, in women, vulvar intraepithelial neoplasia (VIN) and vaginal intraepithelial neoplasia (VAIN) (*884–886*).

Although ART has altered HIV natural history, its effect on HPV and HPV-associated neoplasia is less clear. Certain studies have found reduced persistence/progression of cervical intralepithelial neoplasia (CIN) with use of ART. Conversely, most studies have not reported reduced persistence/progression of high-grade anal intraepithelial neoplasia (AIN) (AIN 2 or AIN 3) among men using ART (*882,892–894*), and most studies of cancer incidence have failed to document decreases in either cervical or anal cancer incidence since the widespread introduction of ART (*882,892,894–899*). Similarly, the incidence of high-grade vulvar neoplasia was not reduced with ART use (*884*), even though rates of low-grade vulvar lesions and anal or genital warts did decrease with ART (*884,900).* Whether ART has an effect on warts among HIV-infected persons is unclear (*884,888,900*). With ART having limited or no effect on HPV-associated cancers, and HIV-seropositive persons living longer, HIV-seropositive women and men will increasingly enter middle age, when the incidence of cervical and other HPV-associated cancers typically increases (*901–903*). Future increases in HPV-associated cancer rates among these patients are possible, particularly for cancers for which no routine screening, such as anal cancer is available. Continued careful monitoring of cancer rates in HIV-positive patients during the highly aggressive antiretroviral therapy (HAART) era is warranted.

Clinical Manifestations

The principal clinical manifestations of mucosal HPV infection are genital, anal, and oral warts; CIN; VIN; VAIN; AIN; squamous cell cancers; and cervical adenocarcinomas. A subset of oropharyngeal cancers are caused by HPV (*877*). HPV6 and 11 also cause recurrent respiratory papillomatosis, a rare condition in which papillomas grow in the respiratory tract.

Genital, Anal, and Oral Warts

Warts (condyloma acuminata) are usually flat, papular, or pedunculated growths on the mucosa or epithelium. The lesions might be a few millimeters to 1–2 centimeters in diameter; multiple lesions might be present. Certain persons with warts are asymptomatic although some have genital itching or discomfort.

CIN, VIN, and Squamous Cell Cancers

No characteristic symptoms are associated with CIN. These lesions are often asymptomatic but might manifest with bleeding. Cervical cancer also might be asymptomatic or might manifest with bleeding, pain, or a palpable mass.

AIN, VAIN, VIN and Oral HPV-Related Disease

No characteristic symptoms are associated with VAIN, VIN, and AIN. These lesions are often asymptomatic but might manifest with bleeding or itching, and external lesions might be visible or palpable. Similarly, squamous cell cancers at these sites also might be asymptomatic or they might manifest with bleeding, pain, or a visible/palpable mass.

Diagnosis

Genital, Anal, and Oral Warts

Diagnosis of genital and oral warts is made by visual inspection and can be confirmed by biopsy, although biopsy is needed only under certain circumstances (e.g., if the diagnosis is uncertain; the lesions do not respond to standard therapy; the disease worsens during therapy; or warts are pigmented, indurated, fixed, bleeding, or ulcerated). No data support the use of HPV tests in the routine diagnosis or management of visible genital or oral warts (*529*).

CIN, VIN, and Squamous Cell Cancers

The same cytology (Papanicolaou or Pap test) and colposcopic techniques used to detect CIN among HIV-seronegative women should be used in HIV-seropositive patients (*904*). Clinicians should be aware of such cytology and histology terms (Table 11). The entire genitalia and anal canal should be inspected carefully for visual signs of warts, intraepithelial neoplasia, or invasive cancer. Cervical cytology, tissue histology, or both should be performed according to the schedule described in the following sections.

After the Pap test, a digital examination of the vaginal, vulvar, and perianal regions and the anal canal should be performed as part of routine evaluation to feel for masses.

After an abnormal Pap test, a colposcopically directed cervical biopsy is the principal means of identifying CIN so that the lesion can be treated to prevent development of cervical cancer and to determine appropriate follow-up. For further details, see the section on prevention of cervical cancer.

AIN, VAIN, VIN and Oral HPV-Related Disease

AIN might first be recognized using a combination of visual inspection and anal cytology (termed anal SIL or ASIL), but as with CIN the diagnosis of AIN is principally made using anoscopically directed biopsy. Similarly, VAIN, VIN, and oral dysplasia are recognized through visual inspection and biopsy as needed. See the section on prevention of anal cancer.

Role of HPV Testing

Although a clinical test is available to detect 13 types of oncogenic HPV infection, no recommendations exist for use of this test in HIV-seropositive women. HIV-seropositive women should be referred for colposcopy if their cervical Pap test is interpreted as ASC US, ASC-H (or atypical glandular cells [ACG]), low-grade squamous intraepithelial lesions (LSIL), or high-grade squamous intraepithelial lesions (HSIL) (368,904,905). HPV testing may be used in the management of HIV-seronegative women with a cytologic diagnosis of ASC-US. “is practice has been recommended for similar use in HIV-seropositive women in American Society for Colposcopy and Cervical Pathology (ASCCP) guidelines (906), but at present, insufficient data are available to support this practice. Unlike for HIV-seronegative women, no recommendations exist for the use of HPV testing for triage of HIV-seropositive women aged >30 years with normal cervical cytology (e.g., to less or more frequent Pap tests based on a hybrid capture test) or in follow-up of CIN after treatment. No recommendations are available for HPV testing of anal specimens or other noncervical specimens.

Preventing Exposure

Consistent and correct use of male latex condoms has been associated with 72% reduction in risk for acquisition of genital HPV infection among sexually active college age women (*907*). Evidence confirms that condom use might reduce the risk for HPV-associated disease, including warts, cervical cancer, and CIN in women (*908,909*). Fewer data are available on prevention of HPV infection and HPV-associated conditions among HIV-seropositive patients. Laboratory studies have indicated

that latex condoms provide a sufficient barrier to prevent passage of particles the size of HPV (*908,910*). Although condoms might not prevent transmission of HPV from skin outside the area of condom coverage, they should be used by sexually active HIV-seropositive patients to reduce the risk for transmission or acquisition of sexually transmitted infections **(AII).**

A vaccine targeted against HPV16 and HPV18 (the two HPV types responsible for 60%–70% of cervical cancers) and HPV6 and HPV11 (which cause most anogenital warts) was licensed and recommended for use in 2006 (*911,912*). This quadrivalent HPV vaccine was efficacious in preventing HPV infection and high-grade CIN associated with vaccine-related HPV types among young HIV-seronegative women (*913–916*). A second vaccine targeting HPV16 and 18 has had similar efficacy. No data are available regarding the safety, tolerability, immunogenicity, or efficacy in HIV-infected women, and specific recommendations for HIV-seropositive women await data from ongoing studies. However, given the safety of other noninfectious vaccines in HIV-seropositive patients, the HPV vaccine is not absolutely contraindicated in HIV-seropositive women, and it may be used in circumstances when the clinician believes clinical benefit can be derived. The HPV vaccine has not demonstrated therapeutic benefit to treat existing HPV-related lesions in either HIV-seropositive or HIV-seronegative women, and women who have already acquired one sexually transmitted infection (e.g., HIV infection) are presumably more likely to have acquired others (e.g., infections with various HPV types). No published studies support using the HPV vaccine to prevent HPV infection and associated lesions of the anus, penis, or oral cavity; the vaccine is not currently approved for use in men in the United States. As in HIV-seropositive women, no data on the safety or efficacy of the HPV vaccine in HIV-positive men are available.

Preventing Disease

Preventing Cervical Cancer

See the guidelines for the use of cytology and biopsy to diagnose CIN. Also see section regarding treatment of CIN.

After obtaining a complete medical history, including the history of previous cervical disease, HIV-seropositive women should have a pelvic examination and a Pap test. The Pap test should be obtained twice during the first year after diagnosis of HIV infection and, if the results are normal, annually thereafter **(AII).** If the results of the Pap test are abnormal, care should be provided according to the Guidelines for Management of Women with Abnormal Cervical Cancer Screening Tests by ASCCP (*904*).

Regardless of $CD4^+$ count, plasma HIV viral load, or antiretroviral treatment status, colposcopy and appropriate directed biopsy are recommended for HIV-seropositive women with cytological reports of "atypical squamous cells, cannot exclude high grade SIL" (ASC-H), **(BII),** LSIL **(AII),** HSIL **(AII),** or squamous cell carcinoma **(AII)** (*529*). HPV testing may be used in the management of HIV-seronegative women with a cytologic diagnosis of ASC-US. This has been recommended for similar use in HIV-seropositive women in recent ASCCP guidelines (*904*). However, published data are limited, conflicting, and insufficient to support the use of HPV DNA testing in triage of ASC-US among HIV-seropositive women **(DIII)**. A prudent plan is to perform routine colposcopy for HIV-seropositive women with ASC-US **(CIII).**

Among women with ASC-US on a Pap test, if a biopsy-confirmed CIN is absent and the colposcopic exam was adequate, follow-up with cervical cytology in 12 months is recommended **(BIII),** with referral back to colposcopy if results of ASC-US or greater are obtained. After two repeated results negative for intraepithelial lesion or malignancy, an affected woman can return to routine annual cytological screening **(AII).** ASCCP guidelines should be followed if the colposcopic exam is not adequate or when CIN is found.

If no CIN 2 or 3 lesion is identified at colposcopy among women with ASC-H, and a review of the results confirms the reading of ASC-H, cytological follow-up is recommended at 6 and 12 months **(CIII).** Women with ASC-US or greater on repeat cytology should again be referred for repeat colposcopy **(BII).**

For women referred to colposcopy for LSIL, if the colposcopy is satisfactory (entire squamocolumnar junction can be visualized with the colposcope) and no lesion or CIN is identified, follow-up with repeat cytological testing at 6 and 12 months is recommended **(BII).** ASCCP guidelines should be followed if the colposcopy is unsatisfactory or CIN is found.

A cytological result of HSIL identifies a woman at high risk for high-grade CIN or invasive cervical cancer. An immediate loop electrosurgical excision or colposcopy with endocervical assessment is an acceptable method for managing women with HSIL **(BII).** ASCCP guidelines should be followed if the colposcopy is satisfactory and no lesion or only CIN 1 is identified, or the colposcopy is unsatisfactory, or CIN 2 or 3 is found.

AGC on cytology is associated with greater risk for CIN and glandular neoplasia than ASC-US or LSIL. The Bethesda system has classified AGC into three categories: AGC, either endocervical, endometrial, or glandular cells not otherwise specified ("AGC NOS"); AGC, either endocervical or glandular cells favor neoplasia ("AGC favor neoplasia"); and endocervical adenocarcinoma in situ (AIS). Colposcopy with endocervical sampling is recommended for all the subcategories of AGC and AIS **(AII).** Endometrial sampling is recommended in

conjunction with colposcopy and endocervical sampling in women 35 years of age and older **(BII).** ASCCP guidelines should be followed for women under the age of 35 and for subsequent evaluation of AGC.

For women with "AGC favor neoplasia" or AIS, those with normal colposcopy should undergo a diagnostic excisional procedure (e.g., cold knife excision, loop electrosurgical excision) **(BII).** If the initial colposcopy is normal in a woman with "AGC NOS," repeat cytology is recommended at 4–6-month intervals until four consecutive tests negative for intraepithelial neoplasia are obtained before returning to routine cytological screening **(BIII).** If abnormal cytology, including ASC, is obtained on follow-up cytology, repeat colposcopic examination or referral to a specialist is recommended **(BIII).**

Preventing Vaginal and Vulvar Cancer

In keeping with recommendations for HIV-seronegative women, routine screening of HIV-seropositive women for vaginal cancer following a hysterectomy for benign disease is not recommended, but women with a history of high-grade CIN or invasive cervical cancer are at increased risk and should be followed with a regular vaginal cuff Pap test **(AIII)** (*917,918*). For patients with abnormal vaginal cuff Pap tests with no visible vaginal colposcopic abnormalities, vaginal colposcopy and use of Lugol's iodine to stain the vagina are recommended **(AIII).** Vaginal colposcopy is also indicated in the presence of concomitant cervical and vulvar lesions (*919,920*). Classification of VAIN parallels that of the cervix (i.e., VAIN 1, VAIN 2, and VAIN 3).

No screening procedure is available for vulvar cancer. However, for HIV-seropositive women with a past history of cervical or VAIN/cancer, an inspection of the vulva with or without colposcopy should be encouraged as part of their regular follow-up **(CIII).** Diagnosis of VIN/cancer should be confirmed with a biopsy **(AII).** A wedge biopsy under local anesthesia is usually done.

Preventing Anal Cancer

High-grade AIN (AIN 2 or 3) has the potential to progress to invasive anal cancer (*921,922*). Evidence from multiple studies demonstrates that HIV-seropositive MSM and HIV-seropositive women are at increased risk for AIN 2 or 3 and are at increased risk for anal cancer compared with the general population. The incidence of anal cancer has not declined since the widespread introduction of ART (*899*). This evidence and a cost-effectiveness analysis projecting that screening and treatment for anal precancerous lesions detected by Pap tests provide clinical benefits comparable to other OI prevention measures for HIV-seropositive persons (*923*), anal cytology screening of HIV-seropositive MSM and of women might be useful preventive strategies. However, studies of screening and treatment programs for AIN 2 or 3 should be implemented before definitive recommendations for anal cytology screening can be made. No national recommendations exist for routine screening for anal cancer (*529*). Until such time, certain specialists recommend an annual digital rectal examination as an important procedure to detect masses on palpation that might be anal cancer **(BIII)** (*924*). In addition, certain specialists recommend anal cytologic screening for HIV-seropositive men and women **(CIII).** If anal cytology is performed and indicates ASC-US or ASC-H, LSIL, or HSIL **(BIII)**, then it should be followed by high-resolution anoscopy (HRA). Visible lesions should be biopsied to determine the level of histologic changes and to rule out invasive cancer **(BIII).** See section on treatment for details of treatment of AIN.

Preventing Other HPV-Associated Cancers Among HIV-Seropositive Men and Woman

Other cancers that have been associated with HPV infection among HIV-seropositive men and women include oropharyngeal squamous cell and penile cancers (*841,897,925*). Prevention options for these cancers are unclear. Circumcision might reduce the risk for penile cancer as documented in one study (*926*); however, the benefits of circumcision to prevent HPV infection and penile cancer have not been studied in a randomized clinical trial or among HIV-seropositive men. No national recommendations exist for screening for oropharyngeal or penile cancer or precancerous lesions among those with HIV infection.

Treatment of HPV-Associated Genital and Anal Lesions

Treatment of Genital and Oral Warts

Treatments are available for genital warts, but none is uniformly effective (*529*). No single treatment has been demonstrated to be superior to any other, and no single treatment is ideal for all patients or all warts. Recurrences are common regardless of the modality (*927*). Data are limited on the response of HIV-seropositive patients to the available treatments for genital warts. In the absence of data specific to the HIV-seropositive population, guidelines for the treatment of STDs for HIV-seronegative patients should be followed (*529*). Data are insufficient to recommend a single treatment modality for all patients, and more than one treatment option might be required for refractory or recurrent lesions among patients with HIV infection.

Patient-applied treatments are generally recommended for uncomplicated external warts that can be easily identified by the patient and consist of the following options:

Podophyllotoxin (e.g., podofilox [0.5% solution or gel]) is an antimitotic agent that should be applied topically to warts twice daily for 3 days, followed by 4 days of no therapy. Treatment can be repeated weekly for up to four cycles **(BIII).** The efficacy is 40%–60% in immunocompetent subjects (*928,929*).

Imiquimod (5% cream) is a topical cytokine inducer that recruits an inflammatory response to the site of the wart. Patients should apply the cream once daily at bedtime three times a week for up to 16 weeks. The treatment area should be washed with soap and water 6–10 hours after the application **(BII).** The efficacy of imiquimod in immunocompetent persons is 30%–70%; the overall response in HIV-seropositive persons might be lower than in immunocompetent persons (*930–932*).

Provider-applied treatments are typically recommended for complex or multicentric lesions or those lesions inaccessible to patient-applied treatments. These include intra-anal and vaginal warts. Options are summarized as follows:

Cryotherapy (liquid nitrogen or cryoprobe) destroys lesions by thermal-induced cytolysis. Liquid nitrogen should be applied until each lesion is thoroughly frozen and repeated every 1–2 weeks. Certain specialists recommend allowing the lesion to thaw and freezing a second time in each session **(BIII).** The efficacy of cryotherapy is 60%–80%.

Trichloroacetic acid (TCA) or bichloroacetic acid (BCA) (80%–90%) act as caustic agents to kill wart tissue. Providers should apply a small amount to warts only and allow them to dry, at which time a white "frosting" develops. If an excess amount of acid is applied, the treated area should be powdered with talc, sodium bicarbonate, or liquid soap to remove unreacted acid. The treatment can be repeated weekly for 3–6 weeks **(BIII).** The expected efficacy is 60%–80%.

Surgical treatments (tangential scissor excision, tangential shave excision, curettage, electrosurgery, electrocautery, infrared coagulation) can be used for external genital and anal warts **(BIII).** Laser surgery also can be used, but is usually more expensive **(CIII).** The efficacy of surgical removal can approach 100%, depending on the location of the lesions.

Podophyllin resin is a crude extract that contains podophyllotoxin and other cytotoxins and induces wart necrosis after topical application. It is prepared as a 10%–25% suspension in tincture of benzoin. It is applied to all lesions by the provider (up to 10 cm^2 of skin area) and then removed by washing a few hours later. Applications can be repeated weekly for 3–6 weeks **(CIII).** Efficacy is 20%–80%. It is usually only applied to external lesions and use of podophyllotoxin is preferred over podophyllin resin.

Other treatments might be options, but because of limited available data, difficult administration, or possible side effects these treatments should be considered only if the treatments described above are ineffective. In limited, uncontrolled studies, topical application of cidofovir has reported activity against genital warts **(CIII)** (*933,934*). No topical formulation is commercially available. Intralesional interferon has been used for the treatment of genital warts but because of cost, difficult administration, and potential for systemic side effects (i.e., fever, fatigue, myalgias, and leukopenia) it is not recommended for first-line treatment **(DIII).** Among non-HIV–infected persons, the overall efficacy of interferon in treating genital warts is not superior to other therapies and it has not been specifically studied for efficacy among HIV-infected persons.

Oral warts can be located on various surfaces in the mouth. In contrast to other oral manifestations of HIV, an increased prevalence of oral warts in patients on ART has been reported from the United States and the United Kingdom (*935,936*). No randomized trials of treatment of oral warts exist. Treatments include surgical excision and cryotherapy; some topical modalities have had success (*937*).

Treatment of CIN and Cervical Cancer

HIV-infected women with CIN should be managed by a specialist. Women having undergone satisfactory colposcopy with biopsy-confirmed CIN 1 preceded by ASC-US, ASC-H, or LSIL cytology can be followed with repeat cytological assessment at 6 and 12 months **(BII)**. Referral to colposcopy is indicated if follow-up shows ASC or greater **(AII).** After two consecutive negative cytology tests, annual cytologic screening can be resumed **(AII)**. If CIN 1 persists for at least 2 years, either continued follow-up or treatment with excision or ablation is acceptable **(AI)**. ASCCP guidelines should be followed if the colposcopy is unsatisfactory, the endocervical sampling contains CIN, or the patient has been previously treated **(AIII)** (*938*). A diagnostic excisional procedure or observation with colposcopy and cytology at 6- month intervals for 1 year is acceptable for CIN 1, preceded by HSIL or AGC-NOS **(BIII).** Women with satisfactory colposcopy and biopsy-confirmed high-grade CIN can be treated with either ablation (cryotherapy, laser vaporization, electrocautery, diathermy, and cold coagulation) or excisional methods (loop electrosurgical excision procedure [LEEP], laser conization, cold knife conization) **(AI)**. In patients with recurrent high-grade CIN, diagnostic excisional methods are recommended **(AII)**. Hysterectomy is acceptable for treatment of recurrent/persistent biopsy-confirmed high-grade CIN **(BII)**. ASCCP guidelines should be followed if colposcopy is unsatisfactory (*938*).

After treatment of high-grade CIN, follow-up with cervical cytology or combination of cervical cytology and colposcopy at 6-month intervals with at least two cytologic results of "negative for squamous intraepithelial lesion or malignancy" is

acceptable **(AI).** Annual cytology can be done thereafter. Any ASC or greater requires colposcopy **(AII).**

Invasive cervical cancer is usually treated by radical hysterectomy with lymph node dissection or by radiation therapy for advanced disease. If cone biopsy or loop excision reveals microinvasive cervical cancer with clear margins, a simple hysterectomy can be done. An alternative for women with microinvasive lesions who want to preserve their fertility is local surgical procedure such as LEEP or cone biopsy with careful follow-up.

Treatment of VIN and Vulvar Cancer and of VAIN and Vaginal Cancer

Various treatment modalities for VIN are available, including local excision, laser vaporization, or ablation. Management of vulvar cancer must be individualized in consultation with a specialist. The cornerstone of the treatment of vulvar cancer is surgery. There is no standard operation and the emphasis is on the most conservative operation consistent with curing the disease. Radical vulvectomy with "en bloc" inguinofemoral lymphadenectomy has led to a favorable prognosis but with substantial morbidity (*939,940*). Further studies are needed to determine the optimal combined modality treatments. Radiation is also an option for some patients. The optimal treatment recommendations for HIV-seropositive women with advanced vulvar cancer remain unclear.

Similarly, treatment of VAIN is individualized in consultation with a specialist and depends on the patient's medical condition and the location and extent of the disease. Various methods of local tissue ablation to more extensive surgery have been used to treat VAIN. Treatment options include topical 5-fluorouracil, 5% imiquimod cream, laser vaporization with CO_2 laser, and excisional procedures with electrosurgical loops or a scalpel excision. On occasion, total vaginectomy may be necessary. Radiation therapy is the treatment of choice for vaginal cancer.

Treatment of AIN and Anal Cancer

For AIN, no randomized, controlled therapeutic trials have been reported and data are insufficient to recommend a specific treatment approach. Treatment decisions are based on assessment of the size and location of the lesion and the grade of histology. The least aggressive approaches should be tried first whenever possible (**CIII**): for example, several different treatments, including topical 5-fluorouracil, photodynamic therapy, infrared coagulation, cryotherapy, laser therapy, and surgical excision, have been described in small open-label studies (*881,922,941–944*). In retrospective analysis, infrared coagulation has been proven to have moderate efficacy to treat AIN 2 or 3 in HIV-seropositive patients **(CIII)** (*943*) and was safe and well tolerated in this population in a recent AIDS Malignancy Consortium study. No indications exist for radiation therapy for patients with AIN in the absence of evidence of invasive cancer **(EIII).**

The results of studies do not indicate that treatment for AIN should be modified for patients receiving ART. Conversely, no evidence indicates that ART should be instituted or modified for the purpose of treating AIN **(CIII)**.

Treatment of anal cancer must be individualized in consultation with a specialist.

Treatment of HPV-Associated Disease at Other Sites, Including the Penis and Mouth

Penile and some oral cancers are associated with HPV infection. Treatment options do not differ between HIV-seropositive and HIV-seronegative men and women. Data suggest a more favorable prognosis among HPV-associated oropharyngeal cancers compared with non-HPV associated oropharyngeal cancers (*945*).

Monitoring and Adverse Events, Including Immune Reconstitution Inflammatory Syndrome (IRIS)

Monitoring is required during and after treatment of genital warts because each of the treatments has associated toxicity and recurrences are common after treatment. Patients can be monitored by physical examination for evidence of recurrence. The major toxicity of podophylloxotin and topical podophyllin resin is local skin irritation. Also, if podophyllin is applied to a large treatment area, systemic absorption can cause nausea, vomiting, and CNS effects. The major toxicity of imiquimod is inflammation at the application site. The major toxicity of cryotherapy is local pain. The major side effects of surgical treatment for genital warts are local pain, bleeding, and secondary infection. The major adverse events associated with acid cauterization are local pain and irritation or ulceration of adjacent normal skin. Intralesional interferon can be associated with systemic toxicities of interferon, including fever, fatigue, myalgia, malaise, depression, and other influenza-like symptoms. Infrared coagulation might lead to bleeding and abscess formation.

Because risk for recurrence of CIN and cervical cancer after conventional therapy is increased among HIV-seropositive persons, patients should be followed after treatment with frequent cytologic screening and colposcopic examination according to published guidelines **(AII)** (*853,946*). Treatment of CIN with ablative and excisional modalities can be associated with several adverse events such as pain and discomfort, intraoperative hemorrhage, postoperative hemorrhage, infection, and cervical stenosis.

Each of the treatment modalities for AIN described above is associated with adverse events, primarily pain, bleeding, ulceration, and, rarely, development of abscesses, fissures, or fistulas. Patients may be monitored for adverse events using the methods described above. Treatment of anal cancer is associated with a high rate of morbidity, even when the treatment is successful. Adverse events associated with anal cancer treatment include short-term side effects commonly associated with chemotherapy, such as neutropenia, and longer-term toxicities associated with radiation therapy, such as radiation proctitis.

IRIS has not been described in association with HPV infections.

Management of Treatment Failure

Treatment failure is defined as the persistence or recurrence of lesions after appropriate therapy. For persistent or recurrent genital warts, retreatment with any of the modalities previously described should be considered, preferably with an alternative modality to the one that previously failed **(AIII)**. Genital warts often require more than one course of treatment. A repeat diagnostic excision or hysterectomy is acceptable for women with histological diagnosis or recurrent or persistent CIN 2 or 3 **(BII)** (*853*). Lesion persistence and recurrences after treatment of AIN are common. No data exist to guide the choice of treatment for recurrence of AIN, but either the original therapeutic modality or a different one may be used. Treatment of anal cancer that recurs after standard chemoradiation therapy often consists of abdominoperineal resection of the tumor.

Preventing Recurrence

HIV-seropositive women are at high risk for recurrent CIN after therapy, and HIV-seropositive men and women are at high risk for recurrent AIN. Preventing recurrence requires careful follow-up of patients after treatment. Patients should be monitored with cytologic screening according to published guidelines and, when indicated, colposcopic examination for recurrent lesions **(AI)** (*923,947*)**.** In one study of HIV-seropositive women treated for high-grade CIN, low-dose intravaginal 5-fluorouracil (i.e., 2 grams twice weekly for 6 months) reduced the short-term risk for recurrence (*948*). However, clinical experience with this therapy is too limited to provide a recommendation for use and no follow-up study to confirm these observations has been reported. One study documented that women receiving ART are less likely to have recurrence of CIN compared with women who are not receiving treatment (*949*), but treatment for CIN should not be considered an indication for ART.

No guidelines exist regarding frequency of monitoring after therapy and the monitoring intervals will vary depending on the treatment approach, extent of disease, and other factors. Patients with AIN can be monitored by anal cytology, standard anoscopy, HRA, and biopsy as indicated. Patients with perianal intraepithelial neoplasia can be monitored by visual inspection and biopsy as indicated. Recommendations for monitoring patients for recurrence of anal cancer after completion of therapy are the same for HIV-seropositive and HIV-seronegative persons.

No indication exists for secondary prophylaxis (chronic maintenance therapy) with any of the conventional modalities to prevent recurrence of genital warts, CIN, or AIN.

Special Considerations During Pregnancy

HIV-infected pregnant women with genital warts or anogenital HPV-related neoplasia are best managed by an interdisciplinary team of specialists (e.g.,OB/GYN, infectious disease physician). Pregnancy might be associated with an increased frequency and rate of growth of genital warts (*950–952*). Podophyllin and podofilox should not be used during pregnancy **(EIII)**. Use of podophyllin has been associated with an increased risk for fetal death in several animal models and case reports in humans, but not with congenital anomalies. No experience with imiquimod in human pregnancy has been reported; therefore, its use in pregnancy is not recommended **(DIII)**. No anomalies have been observed among animals with use during pregnancy.

Other topical treatments (e.g., bichloroacetic and trichloroacetic acid) and ablative therapies (i.e., laser, cryotherapy, and excision) can be used during pregnancy.

Transmission of genital HPV6 and 11 from vaginal secretions at delivery is the presumed mechanism of early onset recurrent laryngeal papillomatosis in infants. This condition is rare but is more common among women who have genital warts at delivery (*953*). Cesarean delivery is not known to prevent this condition in infants and children (*950–952*) *(954*). No change in obstetrical management is indicated for women with HPV infection unless extensive condylomata are present that might impede vaginal delivery or cause extensive bleeding (*955–958*).

For evaluation of CIN, all pregnant women should have a Pap test at their initial prenatal visit unless a normal cervical cytology result has been obtained within the past year (*80*). Cytobrush sampling can be done during pregnancy (*959*). Pregnant women with abnormal cervical cytology results should undergo colposcopy and cervical biopsy of lesions suspicious for high-grade disease or cancer **(BIII)**. Endocervical curettage is unacceptable in pregnant women **(EIII)**. Increased bleeding might occur with cervical biopsy during pregnancy.

Pregnant women with ASC-US can be managed the same as nonpregnant women, with the exception that it is acceptable

to defer colposcopy until at least 6 weeks postpartum **(CIII)**. In the absence of invasive disease, treatment of CIN is not recommended during pregnancy. Re-evaluation with cytology and colposcopy is recommended after 6 weeks postpartum. Women with CIN can deliver vaginally.

Pregnant women with suspected cervical cancer should be referred to a gynecologic oncologist for definitive diagnosis, treatment, and delivery planning. Vaginal delivery is not recommended for women with invasive cervical cancer.

The effects of treatment of AIN on pregnancy are not known. Most experts recommend deferral of diagnosis and treatment of AIN until after delivery unless a strong clinical suspicion of anal cancer exists.

Hepatitis B Virus Infection

Epidemiology

Hepatitis B virus (HBV) is the leading cause of chronic liver disease worldwide (*960,961*). In countries with a low prevalence of endemic chronic HBV infection, HBV is transmitted primarily through sexual contact and injection-drug use, whereas perinatal and early childhood exposures are responsible for the majority of HBV transmission in high-prevalence countries. Although risk factors are similar, HBV is transmitted more efficiently than HIV (*960–962*). Up to 90% of HIV-infected persons have at least one serum marker of previous exposure to HBV (*963,964*), and approximately 10% have evidence of chronic hepatitis B (*965–967*). Several genotypes of HBV (A–H) have been identified and are geographically distributed. Genotype A is the most common among patients in the United States and Western Europe.

Clinical Manifestations

Most patients with acute or chronic HBV infection are asymptomatic or have nonspecific symptoms, such as fatigue. When present, symptoms of acute infection might include right upper quadrant abdominal pain, nausea, vomiting, fever, and arthralgias with or without jaundice.

Chronic HBV might lead to mild, moderate, or severe hepatitis with eventual development of cirrhosis and portal hypertension. The physical examination might be notable for signs of cirrhosis such as spider angiomata, palmar erythema, and signs of portal hypertension such as splenomegaly. Uncommon extrahepatic manifestations include polyarteritis nodosa, glomerulonephritis, and vasculitis. Without proper laboratory screening, HBV infection might not be clinically apparent until the onset of end-stage liver disease (ESLD), which is manifested as portal hypertension with ascites, variceal bleeding, coagulopathy, jaundice, or hepatic encephalopathy.

Hepatocellular carcinoma (HCC), which might complicate HBV infection before the onset of cirrhosis, is usually asymptomatic in its early stages. Patients with advanced HCC might experience abdominal pain, symptoms of liver failure, or ESLD, as previously described, or paraneoplastic syndromes (e.g., diarrhea, hypoglycemia, fever).

Diagnosis

Diagnosis of Infection and Disease with Serologic Testing

HIV-infected persons should be tested for HBV infection (*789*). Initial testing for hepatitis B surface antigen (HBsAg), hepatitis B core antibody (anti-HBc total), and hepatitis B surface antibody (anti-HBs) should be performed because these will identify the majority of patients with chronic hepatitis B or who need vaccination to prevent infection. Certain specialists would test for HBsAg and anti-HBs only, excluding anti-HBc, as its presence or absence does not usually affect clinical practice. Chronic HBV infection is defined as a positive HBsAg and anti-HBc or a positive HBsAg, HBV DNA level, or hepatitis B e antigen (HBeAg) on two occasions at least 6 months apart.

Patients with chronic HBV infection should be tested for HBeAg, antibody to HBeAg (anti-HBe), and HBV DNA. Several tests for HBV DNA detection are available; however, the results are not interchangeable. Laboratories report either copies/mL or International Units (IU/mL). The latter is based upon a WHO standard and has greater interlaboratory reproducibility. HBV DNA levels are usually high in chronic infection. Patients with chronic HBeAg-positive infection tend to have higher levels of replicating virus than those with HBeAg-negative infection (10^8–10^{10} copies/mL of blood compared with 10^5–10^6copies/mL). Among HIV-uninfected adults with HBV monoinfection, high HBV DNA levels predict progression of liver disease, development of HCC, and lower responses to therapy. Data characterizing the predictive value in those with HIV/HBV coinfection are lacking.

Some patients test positive for anti-HBc alone, which might signify a false-positive result; exposure in the past with subsequent loss of anti-HBs; or "occult" HBV infection, which can be confirmed by detection of HBV DNA (*968,969*). The clinical significance of isolated anti-HBc is unknown (*968–971*). HIV-infected patients have a higher frequency of isolated anti-HBc, particularly those patients with underlying hepatitis C virus (HCV) infection (*972*). The prevalence of HBV DNA in HIV-infected patients with isolated anti-HBc ranges from 1% to 45% (*973,974*), with most having low levels. Certain specialists recommend that HIV-infected persons with anti-HBc alone should be tested for HBV DNA before vaccination for HBV or before initiating ART because of the risk for reactivation of HBV and the occurrence of IRIS.

Diagnosis of Disease Progression and the Role of Liver Biopsy

Impairment of cellular immunity caused by HIV infection is associated with higher levels of hepatitis B viremia and lower viral clearance rates following acute HBV infection. Limited data indicate that HIV patients with chronic HBV infection are more likely to have detectable HBeAg (*975,976*), lower rates of seroconversion, and an increased risk for liver-related mortality and morbidity (*977*). Despite these differences, the pattern of disease progression is similar to that in monoinfected persons.

Liver biopsy with histologic examination remains a valuable tool for characterizing the activity and severity of chronic hepatitis B and might provide important information in monitoring disease progression and guiding treatment. However, the decision to perform a liver biopsy should be individualized based on the phase of chronic HBV as described below. Liver biopsies might result in major complications, such as excessive bleeding (<0.5%), bile peritonitis (0.09%), and, rarely, internal organ injury, although the overall mortality rate is fewer than 1 in 10,000 (*978,979*).

Patients with a diagnosis of chronic HBV infection who are not treated with antiviral agents should have a complete blood count, platelet count, alanine aminotransferase (ALT), albumin, prothrombin time, and bilirubin monitored at baseline and every 6 months to assess severity and progression of liver disease. Persistent low-level serum aminotransferase abnormalities might be associated with significant liver disease, although normal aminotransferases might also be seen in the setting of cirrhosis. Transient or persistent elevations in serum aminotransferase levels might occur before loss of HBeAg, on discontinuation of anti-HBV therapy, and in association with emergence of HBV drug resistance.

Patients who are HBe-Ag seropositive usually have high HBV DNA levels (>20,000 IU/mL) and abnormal levels of ALT. In some instances, increased levels of ALT might precede a decline in HBV DNA that is accompanied by the loss of HBeAg and development of anti-HBe. Seroconversion marks a transition from active disease to an inactive carrier state (*980*). This transition can be spontaneous or associated with effective HBV treatment. Approximately 8%–12% of monoinfected patients spontaneously convert from a positive to a negative HBeAg and a positive anti-HBe per year (*981*). Spontaneous conversion rates in HIV-infected patients appear to be lower.

Although seroconversion usually implies transition to an inactive carrier state, the re-emergence of abnormal liver enzyme tests might reflect HBeAg-negative chronic hepatitis B disease. Although levels of HBV DNA are usually lower than in HBeAg-positive patients, HBeAg-negative patients experience an unrelenting but fluctuating course of disease progression, with viral loads usually ranging from 10^5 to 10^6 copies/mL (2×10^4–2×10^5 IU/mL), but they can be higher. Thus, in a patient without HBeAg, HBV DNA levels should still be measured. Liver biopsy is recommended in HBeAg-seronegative patients with detectable HBV DNA primarily for persons aged >40 years with "borderline" indications for treatment, such as those with minimally elevated ALT but high HBV DNA level (*982,983*).

Persons who acquire HBV infection perinatally have a high chance of becoming "immune tolerant," with normal aminotransferase levels despite the presence of high levels of HBV DNA. Such patients tend to have minimal disease and liver biopsy is usually not indicated; however, they tend to have HBeAg-positive chronic hepatitis B with elevated ALT levels later in life and remain at risk for the development of HCC, cirrhosis, and flares of hepatitis B (*980*).

The inactive HBsAg carrier state is characterized by a negative HBeAg, normal ALT levels, and an HBV DNA level of <2,000–20,000 IU/mL (or 10,000–100,000 copies/mL). Liver biopsy is not recommended in patients who have cleared the virus (undetectable HBV DNA by PCR assay). However, although their prognosis is usually good, patients in the inactive carrier state remain at risk for reactivation of HBV and development of HCC, but the risk is lower than for those with active HBV replication. This is particularly true for those carriers who are older or who have cirrhosis or coinfection with HCV (*984–987*).

Reactivation of HBV, spontaneous or related to chemotherapy or immunosuppression, can lead to substantial hepatic flares and necroinflammatory liver disease (*988–991*). Although reactivation of HBV can be associated with flares in serum aminotransferases, other etiologies for increased aminotransferase levels, such as hepatotoxicity from ARVs or other drugs or acquisition of another hepatitis virus infection such as hepatitis A, C, or hepatitis delta virus (HDV), must be ruled out (*992–995*).

Patients with chronic hepatitis B are at increased risk for HCC. Among HIV-coinfected persons, who might have an even higher risk for HBV-related HCC than HBV monoinfected patients, monitoring alpha fetoprotein (AFP) level and ultrasound of the liver every 6 months (*996*) might be recommended; however, the effectiveness of this screening strategy has not been studied in this population, and the optimal HCC screening method and interval are not known (*997–999*).

Preventing Exposure

HIV-infected persons should be counseled about the risk for household, sexual, and needle-sharing transmission of HBV; the avoidance of behaviors associated with such transmission;

and the need for any such susceptible contacts to receive hepatitis A and B vaccine as described below. As drug injection via contaminated syringes previously used by infected persons is the primary route of HBV transmission among IDUs, they should be encouraged to stop using injection drugs, preferably by entering a substance abuse treatment program **(AII).** If IDUs are unwilling or unable to discontinue the use of injection drugs, they should be advised not to share needles or drug preparation equipment to reduce the risk for transmission of HBV infection **(BII).** Access to sterile injection equipment may be facilitated through enrollment of IDUs in needle exchange programs (NEPs) (*1000–1002*).

Persons considering tattooing or body-piercing should be informed of potential risks of acquiring HBV, which could be transmitted if equipment is not sterile or if proper infection control procedures are not followed **(AIII)**.

Safe-sex practices should be encouraged for all HIV-infected persons; barrier precautions (e.g., latex condoms) are recommended to reduce the risk for exposure to sexually transmitted pathogens, including HBV **(AII)**.

Preventing Disease

HIV-infected patients who do not have evidence of previous exposure to HBV should be vaccinated with hepatitis B vaccine **(AII)**. Given the decreased response rate to the vaccine in the setting of HIV infection, all HIV-infected patients should have anti-HBs titers obtained 1 month after completion of the vaccine series to document response **(BIII)**. If no response is observed, revaccination should be considered **(BIII)**. HBV vaccination is safe in HIV-infected patients. Transient increases in HIV RNA have been reported after HBV vaccination but do not appear to have clinical relevance (*1003–1005*).

A patient who is seropositive for anti-HBc and anti-HBs has resolved infection and does not need vaccination. However, reactivation of HBV has been observed in immunosuppressed patients. The presence of anti-HBs alone at levels of >10 IU/mL is consistent with seroprotection, usually from vaccination (*1006*), and no further vaccinations are required.

Determining whether hepatitis B vaccine should be administered to patients with "isolated" anti-HBc is not clear because, in addition to a false-positive result, this pattern might signify exposure in the distant past with subsequent loss of anti-HBs or more rarely, occult HBV (*1007*). One approach in this setting is to administer one dose of hepatitis B vaccine followed in 2 weeks by anti-HBs testing to determine if an anamnestic response occurs, although the overall response rate described in previous studies is low (16%) (*973,1008,1009*). Larger studies in HIV-uninfected persons with isolated anti-HBc demonstrate that most persons mount a slow, or primary, rather than a rapid, or anamnestic, response after vaccination (*1007*). The majority of HIV-infected patients with isolated anti-HBc are not immune to HBV infection and should be vaccinated with a complete primary series of hepatitis B vaccine **(BII)** (*973,1009*)**.** Certain specialists would test for HBV DNA to rule out occult chronic HBV infection before administering a complete primary series of hepatitis B vaccine.

The immunogenicity of hepatitis B vaccination in HIV-infected adults is 18%–72% (*974*) and is lower than in HIV-seronegative healthy adults, in whom seroconversion rates are >90% (*1010*). Compared with HIV-seronegative healthy adults, HIV-seropositive patients also have lower mean antibody titers and have faster declines of protective antibody over time (*1004,1011,1012*). The negative impact of low $CD4^+$ counts on hepatitis B vaccine responses has been a consistent finding across several studies (*1003–1005,1013–1016*). Other factors associated with lower seroconversion rates include the presence of detectable HIV RNA (*1005,1016,1017*), coinfection with HCV, occult hepatitis B infection, and the general health status of the host (*973,1018–1023*).

Several novel approaches have been investigated to improve primary vaccine responses and those among vaccine nonresponders. These have included increasing the dosage of vaccine (*1003,1005*), the number of doses (*1004*), or use of adjuvant immunostimulatory molecules (*1024*). One double-blind, randomized controlled trial that compared the use of a standard dose (20 mcg) with a double dose (40 mcg) of recombinant hepatitis B vaccine in 210 previously unvaccinated HIV-infected patients demonstrated a substantially higher seroconversion rate with use of the double dose of vaccine, but only in the subgroup of patients with $CD4^+$ counts >350 cells/μL (*1003*). In one study of 32 HIV-infected patients, administration of 1 additional vaccine dose increased the proportion of responders only marginally; however, a sixfold increase in geometric mean titers was demonstrated among those who did respond (*1014*). Doubling the number of vaccine doses in nine HIV-infected patients who did not initially respond to a hepatitis B vaccination series led to protective surface antibody levels in seven persons (*1004*).

On the basis of these data, early vaccination is recommended in HIV-infected patients before the $CD4^+$ count declines to <350 cells/μL **(AII)** (*1014,1025*). However, vaccination should not be deferred for those with negative or indeterminate serologies while awaiting a rise in $CD4^+$ count to >350 cells/μL. Because some HIV-infected patients with $CD4^+$ counts <200 cells/μL do respond to vaccination, vaccination should be performed as previously recommended **(AII)**, with testing for anti-HBs 1 month after completion of the series **(BIII)**. If no response occurs, revaccination should be considered **(BIII).** Certain specialists might delay revaccination until after a sustained increase in $CD4^+$ count is achieved on ART.

One study has suggested that HIV-infected persons with a CD4+ count >350 cells/μL had improved responses when vaccinated with 40 mcg of HBV vaccine on a 0-, 1-, and 6-month schedule (*1003*). Thus, certain specialists recommend initial hepatitis B vaccination in any HIV-infected person with 40 mcg doses of either vaccine at the recommended intervals **(CIII)**. Additional studies are needed to determine optimal vaccination strategies in patients with advanced immunosuppression. ART should be optimized to attain complete suppression of HIV replication and increased CD4+ count, as these factors have been associated with better antibody responses to HBV vaccination **(CIII).** Trials of immunomodulatory agents to improve HBV vaccine responses have led to mixed results, and data are currently insufficient to warrant a recommendation favoring their use **(CIII).**

No vaccination strategy has been consistently effective or adequately studied in vaccine nonresponders. For patients who have not attained an anti-HBs level >10 IU/mL after completion of a primary vaccine series, a second vaccine series is recommended **(BIII).** Certain specialists recommend that in such cases, revaccination with 40 mcg doses of either of the available vaccines be considered, regardless of which dose was used initially **(CIII)**. Anti-HBs should be obtained approximately 1 month after completion of the vaccine series to assess vaccine response **(BIII)** (*1025*). Certain specialists suggest once yearly evaluations for patients who have an ongoing risk for HBV acquisition **(CIII)**, as recommended for dialysis patients (*1026*). This is particularly important in patients who have a low level of protective antibody, because loss of antibody over time is related to the maximal antibody response after vaccination, and loss of antibody among dialysis patients has translated into loss of protection against HBV infection (*1006,1027,1028*). Immune-competent hepatitis B vaccine responders, however, remain protected against the development of clinical disease and chronic HBV infection despite subsequent declines in anti-HBs to <10 IU/mL (*1027,1029*).

Hepatitis A vaccination is recommended in persons with chronic liver disease, MSM, and IDUs (*529,1030*). HAV-susceptible, HIV-infected persons with risk factors for HAV infection should receive hepatitis A vaccination (**AII**). As with hepatitis B vaccination, the response to hepatitis A vaccination is reduced in those with CD4+ counts <200 cells/μL. Certain specialists might delay hepatitis A vaccination until the CD4+ count is >200 cells/μL on ART (**CIII**). Antibody response should be assessed 1 month after vaccination; nonresponders should be revaccinated **(BIII)**.

Treatment of Disease

Patients with chronic hepatitis B disease should be advised to avoid or limit alcohol consumption because of its effects on the liver **(AIII)**. In addition, they should be counseled about the risk for household, sexual, and needle-sharing transmission and the need for any such susceptible contacts to receive hepatitis A and B vaccine as described above.

The goals of anti-HBV therapy are to prevent disease progression and reduce HBV-related morbidity and mortality. Treated patients rarely become HBsAg negative because HBV reservoirs generally are not sufficiently reduced by available anti-HBV therapy. HBV might persist in the liver, in the absence of circulating virus, as closed circular DNA (ccDNA), which can lead to reactivation after chemotherapy, steroid use, or immunosuppression, including HIV-associated immunosuppression. Nevertheless, studies in HBV-monoinfected patients suggest suppression of HBV DNA to a "nonreplicative" state, HBeAg seroconversion from positive to negative, seroconversion to anti-HBe, loss of HBsAg, and acquisition of anti-HBs are all associated with decreased incidence of HCC and improved survival; thus, these surrogates also are goals of anti-HBV treatment for HIV-infected persons. For HBeAg-negative patients with increased ALT and HBV DNA levels, long-term antiviral suppression might be indicated because treatment discontinuation has been associated with virologic relapse.

In HIV/HBV-coinfected patients, the imperative to treat depends not only on the level of HBV viremia and degree of biochemical and/or histologic disease, but also on whether the patient is initiating ART. HIV/HBV-coinfected patients initiating ART should be treated for HBV, regardless of the level of HBV DNA, either with antiviral agents active against both HIV and HBV or with antiviral agents with independent activity against each virus (**CIII**). This approach might reduce the risk for IRIS, particularly in those who have advanced immunodeficiency. If ART is not required, then initiation of treatment for HBV is the same as for HBV-monoinfected patients. Anti-HBV therapy is indicated for persons with abnormal ALT levels and HBV DNA levels >20,000 IU/mL (>10^5 copies per mL) for HBeAg-positive patients, and abnormal ALT levels with HBV DNA levels >2,000 IU/mL (>10^4 copies per mL) for HBeAg-negative patients **(CIII)**. However, because of the increased rate of liver disease progression in the setting of HIV infection, certain specialists recommend treatment at any level of detectable HBV DNA, especially in the setting of elevated ALT levels **(CIII)**. In addition, anti-HBV treatment should be considered for HIV-infected patients with low but detectable HBV DNA levels who have substantial histologic inflammatory activity or fibrosis on liver biopsy **(CIII).** Certain specialists recommend treatment of those with advanced fibrosis or cirrhosis on liver biopsy with any detectable HBV DNA level, provided other causes for chronic liver disease have been eliminated (*1031*).

Treatment options for HBV in the setting of HIV infection must consider the goals of therapy and the effect treatment might have on both HIV and HBV replication. FDA-approved antiviral drugs available for treatment of HBV infection include lamivudine, adefovir, entecavir, tenofovir, standard interferon-alfa, pegylated interferon (pegIFN)-alfa, and telbivudine. FDA-approved HIV antiretroviral medications, such as emtricitabine (and its single-pill combination with tenofovir), also have substantial activity against HBV, although they are not approved for this indication.

IFN-alfa-2a and -2b, administered in subcutaneous doses of 5 MU daily or 10 MU three times per week, are approved for the treatment of chronic hepatitis B disease among HIV-uninfected persons, but not among HIV-infected patients. Approximately one-third of HIV-seronegative patients will clear HBeAg with either of these IFN regimens (*996,1032*), and the response is sustained among 80%–90% of persons followed for 4–8 years (*1033*). PegIFN alfa-2a is also approved for treatment of HBV among HIV-seronegative patients and in clinical trials was proven to be superior to standard IFN for both HBeAg-positive and HBeAg-negative patients when used for 48 weeks (*1034,1035*). No published data exist regarding efficacy of either formulation of pegIFN in the setting of HIV/HBV coinfection. Although HIV replication can be suppressed by pegIFN alfa (*1036*), no evidence indicates that IFN selects for resistance mutations that will influence future therapeutic options for HIV infection. On the basis of this information, pegIFN alfa-2a might be considered for treatment of HBV infection in HIV-coinfected patients irrespective of the need for ART for treatment of their HIV infection **(CIII)**.

Among HIV-uninfected persons, the response rates to lamivudine-containing regimens are >50% in patients with ALT levels >5 times the ULN and 20%–35% among patients with ALT levels 2–5 times the ULN. Lamivudine is active against hepatitis B and HIV at the 150 mg twice-daily dose used for treatment of HIV infection. HBeAg seroconversion rates appear to be low in HIV-infected patients treated with this agent. Resistance to lamivudine occurs in the majority of patients on chronic therapy; the rates of resistance appear to be even higher in patients with HIV infection (*1037*). Because lamivudine is active against both HBV and HIV and monotherapy for HBV will select for HIV resistance mutations, lamivudine should not be used for treatment of HBV in HIV-infected patients who are not also being treated with combination ART for their HIV infection **(EIII)**.

Emtricitabine is active against HBV and HIV. Because of its structural similarities to lamivudine, emtricitabine also is associated with a relatively rapid onset of HBV and HIV drug resistance, and cross resistance of HIV and HBVto lamivudine also should be assumed in patients with suspected lamivudine resistance. As with lamivudine, emtricitabine should not be used for treatment of HBV in coinfected patients who are not being treated with combination ART for their HIV infection **(EIII)**.

Adefovir is effective in both HBeAg-positive and HBeAg-negative patients with chronic HBV infection, although viral suppression occurs at a slower rate than with other agents and rates of seroconversion are low. Despite the slower viral load decline, the onset of drug resistance to adefovir is delayed compared with lamivudine or emtricitabine. The addition of adefovir to lamivudine in HIV/HBV-coinfected patients with HBV lamivudine resistance has been associated with an approximately 4-$\log_{10}$ decline in HBV viremia (*1038*). During 4 years of treatment, 25% of patients in one study attained complete virologic suppression. In those with detectable HBV viremia, no adefovir-associated mutations were observed. In coinfected patients, initial reports suggested that adefovir dipivoxil might be associated with selection of HIV-associated mutations (K65R and K70E) (*1039*). However, additional studies have not demonstrated selection of these mutations after up to 4 years of therapy, although minority variants could have been missed (*1040*). On the basis of these data, adefovir might be considered for treatment of HBV in HIV-coinfected patients, irrespective of the need for their HIV infection. (**CIII**).

Tenofovir, 300 mg daily, is more potent in vitro than adefovir, 10 mg daily, against HBV and data from human clinical trials and clinical experience indicate it is also active against lamivudine-resistant and wild-type HBV. A prospective, randomized, double-blind, placebo-controlled, noninferiority trial comparing tenofovir to adefovir in HIV-infected patients demonstrated benefit of tenofovir in the setting of lamivudine-resistant HBV (*1041*). Two recent randomized, double-blind studies, one with HBeAg-negative and another with HBeAg-positive patients, demonstrated the superiority of tenofovir over adefovir related to HBV DNA suppression in HBV-monoinfected patients (*1042,1043*). As with lamivudine and emtricitabine, tenofovir should not be used for treatment of HBV in HIV-coinfected patients who are not receiving combination ART for treatment of their HIV infection because of the risk for acquiring HIV-associated resistance mutations **(EII)**.

Entecavir is approved for treatment of HBV and in clinical trials was proven to be more effective than lamivudine with regard to the rate of HBV DNA decline and viral suppression at 48 weeks of treatment. Of the available agents for treatment of HBV other than interferon, entecavir is associated with the slowest onset of resistance, which usually requires a background of mutations at M204V/I and L180M to emerge. Literature in HIV/HBV coinfection is limited, but in a trial of 68 coinfected, lamivudine-experienced patients who were randomly assigned

to receive either entecavir or continue on lamivudine monotherapy, a >3-$\log_{10}$ decline in HBV DNA was noted in the entecavir arm versus the lamivudine arm. No change in HIV RNA levels occurred although these patients were on effective HIV therapy. However, a recent report described three patients who experienced an approximately 1-$\log_{10}$ drop in HIV RNA with initiation of entecavir monotherapy (*1044*). In addition, one patient who had received lamivudine in the past developed an HIV-associated mutation (M184V) during monotherapy with entecavir. A case report of the M184V emerging in a treatment-naïve patient on entecavir monotherapy also has been reported (*1045*). An FDA warning is available at http://www.fda.gov/medwatch/safety/2007/Baraclude_DHCP_02-2007.pdf. On the basis of this information, entecavir should not be used as monotherapy for treatment of HBV in HIV-coinfected patients who are not also receiving combination ART for treatment of their HIV infection because of the risk for developing HIV-associated resistance mutations **(EII).**

Telbivudine has demonstrated efficacy in patients with HBeAg-positive and HBeAg-negative infection and is FDA approved for treatment of chronic HBV infection *(1046,1047)*. It is well tolerated, but like lamivudine, emergence of HBV resistance over time is common. Telbivudine is not active against lamivudine-resistant HBV. Therefore, telbivudine monotherapy is not recommended **(DII).** No clinical data are currently available in HIV/HBV-coinfected patients, but studies are in progress.

Famciclovir is less active than lamivudine against HBV and is not active in lamivudine-resistant HBV; therefore, its use is not recommended **(DII)** (*1048–1050*).

Treatment of HBV in HIV-Infected Patients Who Are Receiving ART

Current guidelines recommend ART for HIV-infected patients who require treatment for HBV infection, regardless of $CD4^+$ count. In such patients, simplifying the treatment regimen can be achieved by offering at least two agents with dual activity against HIV and HBV, considering that a third agent is also required for effective treatment of HIV. Chronic administration of lamivudine as the only active drug against HBV leads to a high rate of HBV drug resistance because of key mutations in the YMDD (M204V/I) motif. One retrospective study suggested that the combination of tenofovir and lamivudine was associated with improved viral suppression compared with either agent alone (*1051*). Other studies also suggested that combination therapy reduces development of drug-resistant mutations (*1034,1052*). For HIV-infected persons, certain specialists recommend combination therapy with two agents active against HBV to reduce the risk for HBV drug resistance, although no results from controlled trials exist to support this strategy **(CII)**. Certain specialists recommend combination therapy with emtricitabine and tenofovir as part of an ART regimen because of ease of administration, tolerability, and dual HBV and HIV activity (**CIII**). Initiation of combination therapy also avoids the administration of sequential monotherapy, which can lead to multi-drug HBV resistance over time (*1053,1054*). The combination of lamivudine and pegIFN is not superior to pegIFN alone and is usually not recommended (*1055,1056*). The strategy of combination therapy versus monotherapy for treatment of HBV is being evaluated in a comparative clinical trial (*1045*).

Entecavir also can be considered in patients with complete HIV suppression who do not demonstrate YMDD motif (M204V/I) mutations in HBV DNA **(CIII)**. If entecavir is used in the presence of the M204V/I mutation, then careful monitoring of HBV DNA levels is indicated because of the increased risk for entecavir resistance in the presence of these pre-existing mutations.

Dual HBV and HCV infections are seen in 3%–5% of HIV-infected persons (*1057*). The replication of one virus usually predominates over another; this phenomenon is referred to as "viral interference." A thorough laboratory evaluation to detect dual HBV and HCV coinfection should include HBV DNA and HCV RNA assays. Among patients infected with HBV, HCV, and HIV, consideration of ART should be the first priority. If ART is administered, then anti-HBV therapy must be included as part of the regimen (as above) and anti-HCV therapy can be introduced as needed. If ART is not desired, IFN-based therapy, which suppresses both HCV and HBV, should be considered **(CIII)**. If IFN-based therapy for HCV has failed, treatment of chronic hepatitis B with nucleoside or nucleotide analogs is recommended **(CIII)**.

Treatment of HBV in HIV-Infected Patients Who Are Not Receiving ART

For patients deferring therapy for HIV infection, agents with sole activity against HBV must be selected for treatment of chronic HBV infection **(BIII)**. The lack of data regarding many of these agents in HIV/HBV-coinfected persons impedes firm treatment recommendations in this population. No data exist regarding the efficacy of pegIFN or the safety or efficacy of telbivudine in HIV-infected persons; adefovir has been evaluated in this population only in those with lamivudine-resistant HBV; and the clinical implications of entecavir-associated HIV resistance mutations prevent its use in this situation. Individualized therapy is necessary; however, certain guiding principles should be followed. The criteria for initiation of treatment for chronic HBV are the same for HIV-infected persons as for those with HBV monoinfection **(CIII)**. Factors that might influence the choice of agent include the immune status

of the patient, the level of hepatitis B viremia, and the patient's HBeAg status. For patients with $CD4^+$ counts >350 cells/μL, adefovir or pegIFN alfa-2a monotherapy for 48 weeks might be considered, with close monitoring of HBV DNA levels and follow-up to evaluate for HBeAg seroconversion **(CIII)**.

Duration of Anti-HBV Therapy

In HIV-seronegative patients, HBeAg seroconversions are sustained among approximately 80% of patients if lamivudine is continued 6–12 months after seroconversion. On the basis of data in HIV-uninfected persons, HIV/HBV-coinfected persons who are HBeAg positive and who become HBeAg negative and anti-HBe positive on lamivudine therapy should be treated for a minimum of 6–12 months beyond HBeAg seroconversion **(BIII)**. All patients receiving ART should continue HBV therapy, even if they have seroconverted to anti-HBe **(CIII)**.

Similar guidance on the duration of therapy can be applied to the use of other HBV active agents, with the exception of peg-IFN-based therapy, which is administered for a standard 48-week course. If HBeAg seroconversion does not occur but viral suppression has been achieved, treatment with anti-HBV agents, if tolerated, should be continued indefinitely **(CIII)**.

Among HIV-seronegative, HBeAg-negative patients with chronic hepatitis B who are treated with lamivudine, ALT and HBV DNA levels might decline, but high rates of relapse have been reported when therapy is stopped (*1058*). Considering these findings, a majority of specialists would continue therapy indefinitely to achieve long-term HBV viral suppression **(CIII)**.

Monitoring and Adverse Events, Including Immune Reconstitution Inflammatory Syndrome (IRIS)

Treatment response should be monitored by testing for HBV DNA and HBeAg at 3-month intervals and at 6–12-month intervals after stopping treatment. A virologic response is defined as a ≥2-log10 decrease in HBV DNA after 6 months of therapy. Ideally, the HBV DNA level after 6–12 months is <20–100 IU/mL based on a real-time PCR assay (*1059*). A maintained virological response is a response that continues while on therapy, and a sustained virological response is one that is still present 6 months after stopping therapy. For patients who are HBeAg positive, loss of HBeAg is also a measure of virological response. Other markers that should be monitored and indicate treatment success include improvement in liver histology based on biopsy; normalization of serum aminotransferases; and, in those with loss of HBeAg, the development of anti-HBe. Sustained loss of HBsAg is considered by some to be a complete response; however, this desirable serologic response is uncommon (**1060**).

Major toxicities of IFN-alfa (pegylated or standard) include influenza-like symptoms (e.g., fever, myalgia, headache, and fatigue), neuropsychiatric abnormalities (e.g., depression, irritability, and cognitive dysfunction), cytopenias (e.g., thrombocytopenia, neutropenia, and reversible reduction in $CD4^+$ count), retinopathy, neuropathy, and exacerbation of autoimmune disease. Depression might be severe enough to trigger suicide. Certain specialists recommend psychiatric evaluation before initiation of IFN-alfa for patients with a prior history of depression and frequent (monthly) monitoring for signs and symptoms of depression during treatment. Hypo- or hyperthyroidism, which is often irreversible, might occur 3–6 months after initiation of therapy with IFN-alfa. As a result, serum thyroid stimulating hormone (TSH) level should be monitored at baseline and periodically (e.g., every 3 months) for the duration of treatment. Depending on the severity of these toxicities and individual patient tolerance, side effects might be dose limiting or interfere with the ability to complete a course of treatment. IFN-alfa is contraindicated in patients with decompensated liver disease.

Adefovir causes renal tubular disease at doses of 30 mg/day or higher, but this toxicity is uncommon at the recommended 10 mg/day dose. Renal toxicity with tenofovir used solely for treatment of HBV has been reported rarely, although isolated cases of increased serum creatinine or renal tubular dysfunction have been observed, and might be more frequent in HIV-infected persons with underlying renal insufficiency or those treated for prolonged periods. Patients on either drug should have baseline urinalysis and creatinine monitoring. Periodic monitoring of serum creatinine and phosphate also should be done in patients receiving adefovir or tenofovir, especially those with underlying diabetes or taking other nephrotoxic agents, because they might be at increased risk for renal toxicity (*1061*).

When anti-HBV therapy with lamivudine, adefovir, or tenofovir is initiated, discontinuation is associated with a flare of liver disease in approximately 15% of cases, with loss of the benefit accrued from previous anti-HBV treatment (*1062*) and possible decompensation of liver disease. Even for patients not receiving ART, certain specialists recommend that when anti-HBV therapies are initiated, they should be continued unless contraindicated or unless the patient has been treated for 6–12 months beyond loss of HBeAg positivity **(CIII)**. However, the risks and benefits of this practice are unknown. If anti-HBV therapy is discontinued and a flare occurs, anti-HBV therapy should be reinstituted because it can be potentially life saving **(BIII)**.

Return of immune competence after ART (or after steroid withdrawal or chemotherapy) can lead to reactivation of HBV-associated liver disease. Any immune reconstitution can lead to a rise in serum aminotransferases, so called "hepatitis

flare" (*1063*), which constitutes IRIS in HIV/HBV-coinfected persons. IRIS might be manifested by dramatic increases in serum aminotransferases as $CD4^+$ counts rise within the first 6–12 weeks after starting ART, with signs and symptoms characteristic of acute hepatitis. After introduction of ART, serum aminotransferases should be monitored closely; some experts recommend monthly for the first 3–6 months and then every 3 months thereafter **(CIII)**. Any association between abnormal aminotransferases and clinical jaundice or synthetic dysfunction (elevated INR and low serum albumin) should prompt consultation with a hepatologist.

All patients with HBV and HIV must receive concomitant anti-HBV therapy when ART is used because these flares can be life threatening. Flares are worse in patients with more severe liver disease, especially cirrhosis. Distinguishing hepatotoxicity or other causes of hepatitis (acute HAV or acute HCV) from IRIS in this setting is difficult. When changing antiretroviral regimens, continuing agents with anti-HBV activity is important because of the risk for IRIS.

All classes of ARVs have been associated with hepatotoxicity as evidenced by substantial elevations in serum aminotransferases (*1064*). ARV-associated hepatotoxicity might be dose dependent or idiosyncratic. The risk for hepatotoxicity has been consistently associated with elevated pre-ART aminotransferases and the presence of HBV or HCV coinfection (*1065–1073*). Despite the increased risk for hepatotoxicity in the setting of HCV or HBV coinfection, the majority of (80%–90%) coinfected patients do not have hepatotoxicity (*1067*), and clinically significant hepatotoxicity is rare; aminotransferases return to baseline in the majority of cases, even if the offending medication is continued (*1066,1074*). Therefore, discontinuing ART is probably not necessary in the presence of hepatotoxicity unless the patient has symptoms of hypersensitivity (fever, lymphadenopathy, rash), symptomatic hepatitis (nausea, vomiting, abdominal pain, or jaundice), or elevations of serum aminotransferase levels >10 times the ULN. However, the development of jaundice is associated with severe morbidity and mortality and should trigger discontinuation of the offending drug(s) (*1075*).

The major problem in managing adverse effects and drug-induced liver injury is determining which medication is the offending culprit and distinguishing drug toxicity from hepatic flares associated with IRIS. Close interaction of HIV clinicians and hepatologists is needed because liver histology might help to differentiate drug toxicity (e.g., eosinophils) from viral hepatitis (e.g., portal inflammation). Spontaneous HBV clearance can be associated with a flare, but occurs rarely in HIV-infected patients. Initiation of ART without anti-HBV therapy might lead to reactivation of HBV. A hepatic flare might also occur when patients must discontinue their ART. Although this should be discouraged, if ART must be discontinued for some reason, patients need to be counseled about the urgent need to continue HBV therapy but without any agents active against HIV to prevent inadvertent mono or dual anti-HIV drug selection pressure favoring development of HIV drug resistance. Elevated aminotransferases might also occur after the onset of drug resistance, which is common and increases over time with medications such as lamivudine (*1037*). Serum HBV DNA testing will help determine if a flare of HBV has occurred. In this situation, HBV resistance testing should be undertaken in consultation with a specialist. Other causes of abnormal liver tests should be sought, including drugs, alcohol, viral hepatitis, and nonalcoholic fatty liver disease.

Management of Treatment Failure

Treatment failure is defined as the presence of HBV DNA greater than 1 $\log_{10}$ above nadir in a patient who is consistently adherent to therapy. Laboratory findings associated with treatment failure include persistent ALT elevations and persistently positive HBeAg for those who had detectable HBeAg at treatment onset.

In HIV-infected persons with lamivudine-resistant HBV, data from a case series of 35 HIV-HBV coinfected patients indicated that treatment with the combination of adefovir and continuation of lamivudine has substantial antiviral effect against lamivudine –resistant HBV (*1076*). Addition of either adefovir or tenofovir appears to lead to greater declines in HBV DNA in lamivudine-resistant coinfected patients (*1041*). Flares of liver disease have been reported with development of resistance to lamivudine. The rate of development of lamivudine resistance is approximately 20% per year among HIV/HBV-coinfected persons treated with lamivudine (*1037*). If lamivudine resistance is suspected or documented, tenofovir or adefovir should be added to lamivudine therapy **(CIII)**. HBV DNA testing might be useful in this setting because increasing levels are associated with emergence of lamivudine resistance or relapse, and stable levels should suggest an alternative cause of acute deterioration. Patients receiving lamivudine who have no detectable HIV RNA, but do have detectable plasma HBV DNA, can be assumed to be lamivudine resistant. Treatment options for patients on ART who have lamivudine-resistant HBV, but fully suppressed HIV, include the addition of adefovir or pegIFN to lamivudine, or tenofovir can be exchanged for one of the nucleoside agents in the ART regimen **(CIII)**. Persons with lamivudine-resistant HBV will have cross resistance to emtricitabine and telbivudine. In the setting of lamivudine-resistant HBV disease, either lamivudine or emtricitabine should be continued because this might decrease development of mutations to other anti-HBV drugs **(CIII)**.

Treatment for ESLD among HIV/HBV-coinfected patients should be managed as it is in HIV-seronegative patients **(BI)**. IFN-alfa is contraindicated in ESLD, but limited data indicate that lamivudine, adefovir, or tenofovir can be used safely (*1037*,*1077*,*1078*). All patients with ascites should undergo paracentesis for analysis to verify that portal hypertension is the etiology and to exclude spontaneous bacterial peritonitis (SBP) (1079). Assessment of the serum-ascites albumin gradient (SAAG) is advisable; SAAG ≥1.1 mg/dL strongly suggests ascites secondary to portal hypertension. Management includes sodium restriction (>2 g/day) to alleviate fluid retention and diuretics. The recommended diuretic regimen is spironolactone alone or combined with furosemide (ratio of 40 mg furosemide: 100 mg spironolactone). Consideration should be given to primary prophylaxis against SBP with the administration of oral antibiotics such as norfloxacin (400 mg/day) or TMP-SMX (1 double-strength tablet/day) in those with an ascites total protein <1 g/dL (*1080*). Secondary antibiotic prophylaxis is recommended for all persons with a history of SBP **(AI)**.

Esophagogastroduodenoscopy (EGD or upper endoscopy) should be performed in all persons who progress to cirrhosis, particularly those with thrombocytopenia, at the time of diagnosis and then every 1–2 years to identify substantial gastroesophageal varices. For persons with varices, nonselective beta blockers (e.g., nadolol or propranolol) are the mainstay of both primary and secondary prevention of variceal hemorrhage; esophageal variceal ligation or banding is another preventive option, particularly for persons who cannot tolerate beta blockers. Hepatic encephalopathy, due to the accumulation of unmetabolized ammonia and other false neurotransmitters absorbed from the gut in the setting of liver dysfunction, might be subtle in early stages (*916*). Preventive measures include restriction of animal dietary protein consumption and the use of nonabsorbable disaccharides (e.g., lactulose) and/or antibiotics (e.g., neomycin, rifaximin).

Patients with HBV-related cirrhosis are at increased risk for HCC (*1081*). Whether additional risk occurs in the setting of HIV infection is unclear (998). Although the optimal screening strategy to detect HCC is unknown, screening for HCC is recommended in patients with documented cirrhosis using hepatic ultrasound imaging performed at 6–12-month intervals **(BIII)** (*1082*). The utility of serum AFP for HCC screening in persons with HIV is unknown, and, because of poor specificity and sensitivity, results of AFP testing should be confirmed with liver imaging studies. In the absence of contraindications, HIV/HBV-coinfected persons with decompensated liver disease and/or early HCC are candidates for orthotopic liver transplantation because HIV infection is not a contraindication to organ transplantation with the use of effective ART (*1083*). Persons with cirrhosis should undergo periodic assessment of their liver disease status through the application of validated prognostic models (Child-Pugh-Turcotte [CPT] Score and Model for End-stage Liver Disease [MELD]) that predict mortality risk and are used to determine the medical need for liver transplantation (*1084*). Where feasible, coinfected persons with well-controlled HIV infection found to have liver decompensation (defined as CPT score ≥7 and/or MELD score >10) or evidence of early HCC should be referred for orthotopic liver transplantation **(BIII)**. Because transplantation does not cure HBV infection, post-transplant HBV treatment is required **(BIII)**.

Special Considerations During Pregnancy

Pregnant women, including HIV-infected women, should be screened for HBsAg. Those who are HBsAg negative and without antibody to hepatitis B should be offered vaccination against hepatitis B. This vaccination can be administered during pregnancy, preferably after the woman is on a stable ART regimen, to prevent the theoretical risk for HIV RNA rebound with vaccination. Treatment of symptomatic acute HBV infection during pregnancy should be supportive, with special attention given to maintaining blood glucose levels and normal clotting status. Risk for preterm labor and delivery might be increased with acute HBV infection.

Treatment of chronic HBV infection is usually not indicated in pregnancy **(DIII),** but HBV positivity must be taken into account when considering therapy options for the HIV-infected pregnant woman.

For women having indications for ART for their own health and expected to continue antiretrovirals postpartum, a regimen including two agents with activity against hepatitis B should be used **(AIII)** (*1085*). Of the antiretroviral agents with activity against hepatitis B, the one most used in pregnancy is lamivudine. Approximately 1,800 cases of pregnancy outcomes after first-trimester exposure to lamivudine have been reported to the Antiretroviral Pregnancy Registry (APR) with no indication of an increased risk for birth defects after exposure (*1086*). Lamivudine has been well tolerated by pregnant women. Tenofovir was not teratogenic in animals, but reversible bone changes at high doses were seen in multiple animal species. A total of 266 cases of first-trimester exposure have been reported to the APR with no increase in birth defects noted (*1086*). Although tenofovir is not usually recommended as a first-line agent in pregnancy, in the setting of maternal chronic HBV infection, it can be included as the second agent with anti-HBV activity, in addition to lamivudine **(BIII)**. Several other antiretroviral agents with activity against HBV, including emtricitabine, adefovir, and telbivudine, have been evaluated and not found to be teratogenic in animals, but experience with these agents in human pregnancy is limited. These agents could

be included in a regimen during pregnancy if other options are not appropriate. Entecavir was associated with skeletal anomalies in rats and rabbits but only at high, maternally toxic doses. Data on use of entecavir in human pregnancy are not available. Cases of exposure during pregnancy to any of the antiretrovirals and HBV drugs listed should be reported to the Antiretroviral Pregnancy Registry (800-258-4263; http://www.apregistry.com). Interferons are not recommended for use in pregnancy, and ribavirin (RBV) is contraindicated in pregnancy. Although IFNs are not teratogenic, they are abortifacient at high doses in monkeys and should not be used in pregnant women because of the direct antigrowth and antiproliferative effects of these agents (*1087*).

The choice of antiretroviral regimen for the pregnant woman with chronic HBV infection who requires antiretrovirals during pregnancy only for prevention of mother-to-child transmission (MTCT) and plans to discontinue therapy after delivery is more complex. Options include starting a triple therapy regimen including two agents with activity against HBV (as discussed above) but stopping therapy after delivery and monitoring closely for a flare of HBV activity, or using a regimen not including drugs active against HBV to avoid a potential flare when discontinued. As an alternative, if only short-term therapy is planned (e.g., starting in the third trimester), consideration should be given to using a combination antiretroviral regimen using lamivudine as the sole agent with activity against HBV **(CIII)**. Certain specialists recommend the first option, using a regimen with dual HBV activity. This recommendation is made even when planning to discontinue postpartum because of the concern about potential IRIS-related flare of HBV activity during pregnancy, even among women with relatively high CD4$^+$ counts, if ARV without anti-HBV activity is used. They believe that treating a potential flare in the postpartum period after discontinuing ARV is associated with less risk than treating an immune-mediated flare during pregnancy. In addition, using drugs with anti-HBV activity during pregnancy will lower HBV levels and potentially decrease the risk for failure of hepatitis B immune globulin (HBIG) and hepatitis B vaccine to prevent perinatal transmission of HBV, which is increased among women with high HBV DNA levels. Certain specialists would use an antiretroviral regimen without anti-HBV activity to avoid the possibility of flare when discontinued postpartum and to avoid the use of tenofovir, a drug with limited experience with long-term use in pregnancy. Certain specialists would use a highly active regimen that includes lamivudine as the only antiretroviral agent with activity against HBV, especially if starting the regimen later in pregnancy because of late care or delayed HIV diagnosis, to avoid use of tenofovir while still treating HBV. Decisions regarding choice of ARV regimen should be made taking into account CD4$^+$ count, HIV RNA levels, time needed for chronic HIV therapy, HBV levels and indications for HBV therapy, gestational age when starting therapy, and patient preference.

Infants born to HBsAg-positive women should receive HBIG and hepatitis B vaccine within 12 hours of birth (**AI**). The second and third doses of vaccine should be administered at 1 and 6 months of age, respectively. This regimen is >95% effective in preventing HBV infection in these infants. Postvaccination testing for anti-HBs and HBsAg should be performed at age 9–15 months because of the infant's ongoing exposure to HBV.

Hepatitis C Virus Infection

Epidemiology

Hepatitis C virus (HCV) is a single-stranded RNA virus that is most efficiently spread through direct blood exposure to contaminated blood or blood products. Both HIV and HCV can be transmitted by percutaneous exposure to blood, through sexual intercourse, and from a mother to her infant. However, the relative efficiency of transmission by these routes varies. HCV is approximately 10 times more infectious than HIV through percutaneous blood exposures, but sexual transmission of HCV is inefficient compared with HIV. Transmission of HIV and HCV through contaminated blood products is now rare because of effective screening of blood and blood-derived products in the United States.

Heterosexual transmission of HCV is uncommon but more likely occurs in persons with partners who are coinfected with HIV and HCV. Likewise, existing data suggest that sexual contact is a relatively inefficient mode of HCV transmission between MSM, but sexual HCV transmission has been increasingly reported among sex networks of HIV-infected men, particularly those engaged in high-risk sex practices. Cases of acute HCV infection are increasingly recognized and reported in this patient population (*1088*).

HCV infection occurs in approximately 2%–5% of infants born to HCV-seropositive mothers. In a majority of studies, the incidence of HCV transmission from mother to infant increases if the mother is coinfected with HIV (*1089–1091*). Overall, rates of HCV vertical and perinatal transmission are relatively low, although increased in the setting of HIV coinfection (*1029,1092*).

In the United States, HIV/HCV coinfection is most prevalent in persons who have a history of hemophilia or injection-drug use, in whom HCV infection rates approach 70%–95% compared with 1%–20% in those who acquired HIV through sex (*1092,1093*). Although studies have suggested that sexual transmission of HCV is inefficient, the exact risk related to dif-

ferent types of sexual activity is unknown. Risk factors for the sexual transmission of HCV include anal-receptive intercourse and concurrent sexually transmitted infection.

Cirrhosis develops in approximately 20% of persons with chronic HCV infection within 20 years after acute infection, although the range and time to development of cirrhosis varies widely. Risk factors for the development of substantial liver disease are older age at the time of infection, male sex, concomitant alcohol use (>20–50 g/day), and advanced immunosupression ($CD4^+$ count of ≤200 cells/μL) (*1094–1096*). Compared with HCV monoinfection, the natural history of HCV infection is accelerated in the setting of HIV (*1097*), with more rapid progression to cirrhosis, decompensated liver disease, hepatocellular carcinoma (HCC), and death (*1098*). Because of its high prevalence and rapid progression, liver disease caused by chronic HCV is a leading cause of death among persons with HIV (*997,999*). Reports of the effect of immune restoration with ART on liver-related mortality are conflicting, with some studies reporting decreases and others little change in the rate of liver-related mortality (*1099,1100*). In addition to liver disease, HCV infection might be associated with changes in cognitive and psychiatric function (*1101*), decreased quality of life (*1102*), and increased prevalence of diabetes mellitus (*1103*), all of which potentially affect HIV management.

The effect of HCV infection on HIV disease progression and immune reconstitution is uncertain (*1093,1104,1105*), although not likely to be clinically relevant based on current observations (*1106*). Patients with underlying viral hepatitis are at increased risk for progression to ARV-related hepatotoxicity (*1068*), although most coinfected patients (approximately 90%) do not have severe hepatotoxicity. The risk for ART-associated hepatotoxicity might be related to the underlying degree of liver fibrosis (*1107*).

Clinical Manifestations

Both acute and chronic HCV infections are typically minimally symptomatic or asymptomatic. Fewer than 20% of patients with acute infection have symptoms characteristic of acute hepatitis, including low-grade fever, mild right upper quadrant pain, nausea, vomiting, anorexia, dark urine, and jaundice. Unexplained elevations of serum ALT or AST levels might be the only laboratory finding during acute infection. Recognition of acute HCV infection is important because antiviral treatment targeting HCV initiated during this period is associated with higher response rates (*1108,1109*).

Chronic hepatitis C infection is often asymptomatic, although complaints of fatigue are common. Serum cryoglobulins might be present but rarely (<5%) cause symptomatic skin (vasculitis), renal (membranoproliferative glomerulonephritis), or neurologic manifestations. HCV-infected patients might experience cutaneous manifestations, including porphyria cutanea tarda. The rate of these manifestations in the setting of HIV is unknown. With progression of liver disease, patients might experience stigmata of cirrhosis with portal hypertension and ESLD, including spider angiomata, palmar erythema, splenomegaly, caput medusa, ascites, jaundice, pruritus, asterixis, and encephalopathy.

Diagnosis

HIV-infected patients should be tested routinely for evidence of chronic HCV infection. Initial testing for HCV should be performed using the most sensitive immunoassays licensed for detection of antibody to HCV (anti-HCV) in blood (*1110*).

False-negative anti-HCV immunoassay results might occur among HIV-infected persons with advanced immunosuppression, but this is uncommon with the most sensitive immunoassays (third-generation assays) (*1090,1111*). If serologic test results are negative or indeterminate and HCV infection is suspected based on elevations of serum aminotransferases or risk factors such as injection-drug use, testing for HCV RNA should be performed (*1112*). True-negative antibody tests might also occur early in the course of acute HCV, in which elevations in serum aminotransferases and detectable viremia are evident before seroconversion; therefore, HCV RNA testing also should be performed when acute HCV infection is suspected.

To confirm the presence of chronic infection, all HCV-seropositive persons should be tested for plasma HCV RNA using a qualitative or quantitative assay. Quantitative HCV RNA level (i.e., viral load) does not correlate with degree of liver damage and does not serve as a surrogate for measuring disease severity, but it does provide important prognostic information about the response to antiviral therapy. Serial quantitative HCV RNA testing should be limited to persons receiving HCV treatment. Diagnostic assays using reverse transcriptase-polymerase chain reaction (RT-PCR) or transcription-mediated amplification (TMA) have been approved by the FDA for qualitative detection of HCV RNA. A single positive HCV RNA result is sufficient to confirm the diagnosis of active HCV infection, but a single negative result cannot exclude viremia because RNA levels might transiently decline below the limit of detection in persons with active infection, especially during the acute phase of infection. A repeat qualitative assay can be performed to confirm the absence of active infection.

Quantitative tests for HCV RNA include quantitative RT-PCR or branched DNA (bDNA) signal amplification assays. Newer real-time PCR assays have excellent sensitivity with lower limits of detection similar to qualitative assays and

a broad dynamic range (e.g., COBAS TaqMan HCV Test; Roche Molecular Systems Inc., Branchburg, NJ). An HCV RNA standard has been established that permits normalization of viral titers in international units (IUs); nonetheless, substantial variability exists among available assays, and if serial values are required to monitor antiviral therapy, continued use of the same quantitative assay for all assessments is strongly recommended.

Six distinct HCV genotypes have been described (*1113*). Genotype 1 infection accounts for approximately 75% of all HCV infections in the United States and approximately 90% of infections among blacks (*1114*). In HCV-monoinfected patients, genotype information is used to guide both the duration of treatment and the dosing of RBV. In contrast, in persons with coinfection, only the dosing of RBV is genotype specific. HCV genotyping should be performed in all HIV-infected persons considering HCV treatment to guide RBV dosing and because it is the best predictor of response to IFN-based treatment and might, therefore, influence the decision to treat and/or perform liver biopsy. Repeat HCV genotype testing is not indicated.

Baseline and periodic monitoring of serum ALT and AST levels should be performed. Levels often fluctuate among patients with chronic HCV infection, regardless of HIV infection, and long periods during which these values are normal might be observed. Although higher serum ALT and AST levels are, to some degree, predictive of more rapid disease progression, (*1091*) substantial liver disease might be present even in the presence of persistently normal ALT levels.

Computed tomography (CT), MRI, and ultrasonography have limited utility in staging liver disease because they are often abnormal only in advanced disease. Ultrasonography is recommended as the initial test for evaluation of persons with liver cirrhosis for the detection of hepatic mass lesions suspicious for HCC. Because of cost, the use of bi- or triphasic CT with contrast or MRI scanning should typically be limited to evaluation of hepatic mass lesions in patients with cirrhosis.

Liver biopsy remains the preferred test for evaluation of HCV-related disease (fibrosis) stage and is useful to assess prognosis and guide treatment decisions. Although ultrasound guidance reduces the risk (*1115*), liver biopsies might result in major complications, including excessive bleeding (<0.5%), bile peritonitis (0.09%), and, rarely, internal organ injury, although the overall mortality rate is <1 in 10,000 (*978,979*). Further, disease staging by biopsy is expensive and subject to sampling error because of the heterogeneity of hepatic fibrosis. In some studies, disease progression has been observed during short periods in persons with minimal fibrosis. Therefore, although liver biopsy is helpful in the evaluation of coinfected persons, it is not required before the initiation of therapy for HCV infection, particularly in patients with a high probability of responding to treatment.

Noninvasive testing strategies to evaluate liver fibrosis are an area of active research. Several tests are available that can reliably separate patients with minimal fibrosis from those with cirrhosis, but these tests fail to distinguish intermediate stages of fibrotic disease (*1116–1119*). Although some tests are proprietary commercial assays (e.g., HCV FibroSURE, Laboratory Corporation of America Holdings), others are based on laboratory tests that are routinely obtained in most HIV-infected persons (FIB-4: age, ALT, AST, and platelet count; APRI: AST-Platelet Ratio Index). Additional studies are evaluating liver stiffness using transient elastography as a surrogate for liver fibrosis (*1120*). Prospective studies are ongoing to determine the test(s) with the best predictive value for disease progression.

Preventing Exposure

The primary route of HCV transmission among IDUs is drug injection via a syringe previously used by an infected person. An increased frequency of injection, a longer duration of injection-drug use, and cocaine use are additional factors that increase the potential for HCV transmission (*1121*). Strategies should be pursued to encourage IDUs to stop using injection drugs, preferably by entering a substance abuse treatment program **(AII).**

In addition to sharing syringes, other factors associated with injection, such as sharing drug solution containers, "cookers," filters, "cottons," and mixing water, also increase the likelihood of HCV transmission (*1122*). If IDUs are unwilling or unable to discontinue the use of injection drugs, they should be advised not to share needles or drug preparation equipment to reduce the risk for transmission of HCV infection **(BII)**. Access to sterile injection equipment can be facilitated through enrollment of IDUs in NEPs (*1000–1002*).

Persons considering tattooing or body piercing should be informed of potential risks for acquiring HCV infection, which could be transmitted if equipment is not sterile or if proper infection-control procedures are not followed **(AIII)**.

Although efficiency of sexual transmission of HCV is relatively low, safe-sex practices should be encouraged for all HIV-infected persons; barrier precautions (e.g., latex condoms) are recommended to reduce the risk for exposure to sexually transmitted pathogens, including HCV **(AII)**.

Preventing Disease

All HIV-infected persons should be screened for active HCV infection. HCV-seronegative persons with elevations in serum aminotransferase levels should be screened for acute infection with assays to detect HCV RNA.

Higher rates of viral clearance have been reported in HIV-infected and -uninfected persons treated with IFN-based therapy for acute HCV infection (*1108,1109*). On the basis of this information and in the absence of contraindications, acutely infected persons (<6 months from the time of HCV exposure) should be routinely offered treatment for HCV infection to prevent the development of chronic HCV infection **(BII).** The optimal time to initiate therapy for acute HCV is unknown but it might be as soon as 8–12 weeks after acquisition of the infection (*1109*) (see Treatment Recommendations).

Chronically infected persons should be counseled about methods to prevent liver damage and HCV transmission, evaluated for chronic liver disease, and considered for treatment of HCV infection. All HIV/HCV-coinfected patients should be offered antiviral treatment to prevent development of HCV-related liver disease complications **(AI)**. All HIV-infected patients with HCV coinfection should be advised to avoid or limit alcohol consumption **(AII)** because alcohol ingestion, particularly in quantities greater than 20–50 grams (approximately 2–5 drinks) per day, might accelerate the progression of liver disease (*1123*). Enrollment of active substance abusers into drug and/or alcohol treatment programs is strongly recommended. Persons with liver disease should limit ingestion of potentially hepatotoxic medications (e.g., acetaminophen <2 grams/day). Because iron overload might worsen liver disease, patients should avoid iron supplementation in the absence of documented iron deficiency.

Because of its increased morbidity, HIV-infected persons who are coinfected with HCV should be tested for previous or concurrent HBV infection. Despite evidence of decreased response to hepatitis B vaccine in immunosuppressed persons, those without previous HBV infection should be vaccinated. Likewise, because acute HAV infection is more likely to be fulminant in persons with underlying hepatitis, HAV-susceptible HIV-infected persons with risk factors for HAV infection should receive hepatitis A vaccination **(AII)**. As with hepatitis B vaccination, the response to hepatitis A vaccination is reduced in those with $CD4^+$ counts <200 cells/μL. Certain specialists recommend delaying hepatitis A vaccination until the $CD4^+$ count is >200 cells/μL on ART **(BIII)**. Antibody response should be assessed 1 month after vaccination; nonresponders should be revaccinated **(BIII)**.

Among coinfected persons with cirrhosis, measures to identify and prevent complications of advanced liver disease are identical to those established in persons without HIV and should be performed routinely **(BI)**. All patients with ascites should undergo paracentesis for analysis to verify that portal hypertension is the etiology and to exclude infection (ascites polymorphonuclear cell count >250 cells/mL) (*1079*). Assessment of the serum-ascites albumin gradient (SAAG) is advisable; SAAG ≥1.1 mg/dL strongly suggests ascites secondary to portal hypertension. Management includes sodium restriction (>2 g/day) and diuretics to alleviate fluid retention. The recommended diuretic regimen is spironolactone alone or combined with furosemide (ratio of 40 mg furosemide: 100 mg spironolactone). Consideration should be given to primary prophylaxis against spontaneous bacterial peritonitis (SBP) through the administration of oral antibiotics such as norfloxacin (400 mg/day) or TMP-SMX (1 double-strength tablet/day) in those with an ascites total protein <1 grams/dL (*1080*). Secondary antibiotic prophylaxis is recommended for all persons with a history of SBP **(AI)**. Upper endoscopy should be performed in all persons with cirrhosis, particularly those with thrombocytopenia, at the time of diagnosis and then every 1–2 years to identify substantial varices (*1124*). For persons with varices, nonselective beta blockers (e.g., nadolol or propranolol) are the mainstay of both primary and secondary prevention of variceal hemorrhage; esophageal variceal ligation or banding is another preventive option, particularly for persons who cannot tolerate beta blockers. Hepatic encephalopathy, caused by the accumulation of unmetabolized ammonia and other false neurotransmitters absorbed from the gut in the setting of liver dysfunction, might be subtle in early stages (*916*). Preventive measures include restriction of animal dietary protein consumption and the use of nonabsorbable disaccharides (e.g., lactulose) and/or antibiotics (e.g., neomycin, rifaximin).

Patients with HCV-related cirrhosis are at increased risk for HCC (*1081*). Whether there is additional risk in the setting of HIV infection is unclear (*998*). Although the optimal screening strategy to detect HCC is unknown, screening is recommended in patients with documented cirrhosis using hepatic ultrasound imaging performed at 6–12-month intervals **(BIII)** (*1082*). The utility of serum AFP for HCC screening in persons with HIV is unknown. Because of relatively poor specificity and sensitivity, results of AFP testing should be confirmed with liver imaging studies. In the absence of contraindications, HIV/HCV-coinfected persons with decompensated liver disease and/or early HCC might be candidates for orthotopic liver transplantation because HIV infection is not a contraindication to organ transplantation with the use of effective ART (*1083*). Persons with cirrhosis should undergo periodic assessment of their liver disease status through the application of validated prognostic models (e.g., Model for End-Stage Liver Disease [MELD] score) that predict mortality risk and are used to determine the medical need for liver transplantation (*1084*). Where feasible, HIV/HCV-coinfected persons with well-controlled HIV infection found to have liver decompensation (defined as Child-Pugh-Turcotte score ≥7 and/or MELD

score >10) or evidence of early HCC should be referred for orthotopic liver transplantation **(BIII)**.

Treatment of Disease

Antiviral treatment for HCV infection should be considered for all HIV-infected persons with acute or chronic HCV infection (**AI**). In the absence of contraindications to pegIFN or RBV, treatment for HCV infection should be offered routinely to persons in whom the potential benefits of therapy are judged to outweigh the potential risks, including (but not limited to) persons with the following conditions **(BII)**:

- HCV genotype 2 or 3 infection
- HCV genotype 1 infection with a low HCV RNA level (<800,000 IU/mL) (although certain specialists might not recommend treatment of patients with HCV genotype 1 infection and low or intermittently undetectable HCV RNA, response to pegIFN plus RBV is improved in those with HCV RNA levels <800,000 IU/mL compared with those with levels above this threshold, which might favor treatment in this group)
- Significant hepatic fibrosis (bridging fibrosis or cirrhosis)
- Stable HIV infection not requiring ART
- Acute HCV infection (<6 months' duration)
- Cryoglobulinemic vasculitis
- Cryoglobulinemic membranoproliferative glomerulonephritis
- Strong motivation to treat their HCV infection

The goals of therapy include eradication of HCV infection; prevention of hepatic fibrosis progression; and, among persons with HCV-related cirrhosis, prevention of ESLD, HCC, and death. Although viral eradication is not anticipated in most treated persons, histologic and clinical benefits of therapy have been observed in the absence of virologic response (*1125*).

On the basis of well-designed, randomized, controlled trials, pegIFN plus RBV is the recommended treatment for hepatitis C in HIV-infected persons **(AI)**. Sustained virologic response (SVR) rates range from 14%–29% for HCV genotype 1 infection and 43%–73% for HCV genotypes 2 and 3 infection (*1036*,*1125*–*1127*). Whereas fixed-dose RBV (800 mg/day) is recommended for HIV-infected persons with genotype 2 or 3 disease, the appropriate RBV dose for persons with genotype 1 disease has not been determined because the pivotal trials studied only fixed-dose RBV. Among HIV seronegative persons with genotype 1, pegIFN plus weight-based RBV (1,000 mg/day for persons weighing <75 kg; 1,200 mg for persons weighing ≥75 kg) was more effective than fixed-dose RBV (*1128*). Although the efficacy of weight-based RBV has not yet been established in coinfected persons, several studies indicate that this strategy is not associated with increased risk for adverse effects (e.g., anemia). Accordingly, certain specialists recommend the use of weight-based RBV combined with pegIFN in HIV-infected persons with HCV genotype 1 disease **(AII)**.

For HCV genotypes 1,4,5, or 6, the recommended treatment regimen is either pegIFN alfa-2a (180 mcg) or pegIFN alfa-2b (1.5 mcg/kg) administered by subcutaneous injection weekly plus oral RBV twice daily (<75 kg or 165 lbs body weight, 600 mg each morning and 400 mg each evening; ≥75 kg or 165 lbs body weight, 600 mg twice daily) for a total duration of 48 weeks **(AI)**. For HCV genotype 2 or 3, the recommended treatment is either pegIFN alfa-2a (180 mcg) or pegIFN alfa-2b (1.5 mg/kg) administered by subcutaneous injection weekly plus oral RBV in a fixed dose of 400 mg twice daily for a total duration of 48 weeks **(AI)**.

The optimal treatment regimen and duration of treatment for acute HCV in coinfected patients has not been determined. Among HIV-seronegative persons, regimens including pegIFN with or without RBV in dosing schedules described above have been administered for 24 weeks' duration with good results. Therefore, in the absence of better information, HIV-infected persons with acute HCV infection should be treated with one of the previously recommended regimens for ≥24 weeks' duration **(BIII)**. Because the efficacy of shorter treatment duration has not been adequately evaluated in HIV-infected persons with acute or chronic HCV infection, the recommended duration of treatment is 48 weeks for chronic infection with all HCV genotypes, including 2 and 3 **(BII)**; on the basis of this information, certain specialists would also treat HIV-infected patients with acute HCV infection for a total duration of 48 weeks.

Treatment for HCV infection with pegIFN plus RBV should NOT be routinely administered to persons in whom the potential risks of therapy are judged to outweigh the potential benefits including (but not limited to) persons with the following conditions **(DII)**:

- Pregnancy, or who are not willing to use birth control;
- Advanced HIV-associated immunosuppression uncontrolled on ART;
- Hepatic decompensation (e.g., coagulopathy, hyperbilirubinemia, encephalopathy, ascites) because liver transplantation, where feasible, should be the primary treatment option for such patients **(CIII)**;
- Severe, uncontrolled comorbid medical conditions (e.g., cancer or cardiopulmonary disease);
- Severe, active depression with suicidal ideation, although HCV treatment may be considered after the successful implementation of psychiatric care and treatment for depression;
- Significant hematologic abnormality (e.g., hemoglobin <10.5 g/dL, absolute neutrophil count <1,000/μL, platelet count <50,000/μL), although HCV treatment

may be considered after the correction of hematologic abnormalities (e.g., treatment of underlying causative conditions and/or use of hematopoietic growth factors);
- Renal insufficiency (creatinine >1.5 or creatinine clearance <50 cc/min), although in such persons, treatment with pegIFN alone may be considered;
- Sarcoidosis because of increased risk for severe disease exacerbation with IFN therapy;
- Active, uncontrolled autoimmune conditions (e.g., systemic lupus erythematosus [SLE] or rheumatoid arthritis) because of increased risk for severe disease exacerbation with IFN therapy.

Patients with contraindications to the use of RBV (e.g., unstable cardiopulmonary disease, pre-existing anemia unresponsive to erythropoietin, renal failure, or hemoglobinopathy) can be treated with pegIFN alfa (2a or 2b) monotherapy **(AII)**. However, substantially lower SVR rates are expected in persons not receiving RBV. Additionally, persons with modifiable contraindications to treatment should be reassessed at regular intervals to evaluate their candidacy for therapy. Active injection-drug use does not represent an absolute contraindication to treatment of HCV infection; treatment of active IDUs should be considered on a case-by-case basis, considering comorbid conditions, adherence to medical care, and risk for reinfection. Management of HCV-infected IDUs is enhanced by linking IDUs to drug treatment programs. Alcohol use negatively affects HCV disease progression and treatment; therefore, alcohol abstinence is strongly recommended before and during antiviral therapy. A history of alcohol abuse is not a contraindication to therapy.

Management of HCV in the Context of ART

The optimal timing of initiation of ART relative to treatment for HCV infection has not been established. Although control of HIV replication and higher $CD4^+$ count as a result of successful ART might be associated with improved response to treatment for HCV infection, this theoretical possibility has not been demonstrated in clinical trials. In addition, data from randomized controlled trials indicate that no substantial relationship exists between pretreatment $CD4^+$ count and higher SVR rates. Also, because persons with $CD4^+$ counts <200 cells/μL have usually been excluded from clinical trials, the efficacy and safety of pegIFN plus RBV has not been established in this population. Therefore, the majority of experts recommend initiation of ART and control of HIV viral replication before initiating treatment for HCV infection for HIV-coinfected patients with $CD4^+$ counts <200 cells/μL **(CIII)**. However, limited evidence suggests that for persons unable to tolerate ART because of hepatotoxicity or who have persistently elevated serum aminotransferase levels (>2 times the ULN), treatment of HCV infection before initiating ART might reduce the risk for recurrent hepatotoxicity or progression of liver disease (*1129*) and should be considered in this situation, regardless of $CD4^+$ count **(CIII)**.

Monitoring and Adverse Events, Including Immune Reconstitution Inflammatory Syndrome (IRIS)

The most appropriate intervals with which to monitor patients for whom treatment for HCV infection is deferred (e.g., those with no or minimal fibrosis or inflammatory changes on liver biopsy) have not been determined, but because of unpredictable progression of fibrosis, even among those with limited fibrosis on initial liver biopsy, serial liver biopsies should be performed every 2–3 years (*1130*).

Assessment of HCV RNA level is the best measure of treatment response and should be performed at baseline and after completion of the first 12 weeks of therapy for HCV infection (*1131*). An early virologic response (EVR) is defined as either an undetectable HCV RNA level or a decrease of ≥2 log10, as measured by quantitative HCV RNA assays, at the end of 12 weeks of treatment. Patients who do not achieve an EVR by week 12 have a limited chance (<3%) of achieving SVR regardless of duration of therapy, and most specialists recommend that treatment should be discontinued after 12 weeks **(AI)**. If an EVR is documented, treatment should be continued **(AI)** and a quantitative or qualitative HCV RNA assay should be performed at the end of 24 weeks of treatment. If HCV RNA levels are undetectable at the end of 24 weeks of treatment, therapy should be continued for a total duration of 48 weeks. If HCV RNA levels remain detectable after 24 weeks of treatment, therapy should be stopped **(AI)**. An HCV RNA assay should be repeated both at the completion of 48 weeks of treatment and 24 weeks after completion of treatment **(AI)**. An SVR is defined as the absence of detectable HCV RNA, using an HCV RNA assay with a lower limit of detection of at least 50 IU/mL, measured at 24 weeks after completion of treatment.

In the context of treatment monitoring, relapse is defined as the absence of detectable HCV RNA at the end of treatment that is not sustained after the discontinuation of therapy. Breakthrough is the re-emergence of detectable HCV RNA following suppression below the limit of detection despite the continuation of therapy. Virologic failure or nonresponse is defined as the failure to suppress HCV RNA below detection at any time during treatment. Certain specialists recommend the continuation of treatment despite virologic failure in persons with advanced liver fibrosis based on the observation that approximately one third of coinfected patients who underwent liver biopsy had histologic improvement in fibrosis, despite the absence of a virologic response in one trial (*1125,1132*).

However, more recent data suggest this approach is ineffective and it is not recommended.

HIV-infected patients who achieve an SVR should be monitored with serial HCV RNA testing at 6–12 month intervals for an additional 1–5 years to exclude late relapse or reinfection with HCV, especially those at risk for continued exposure **(CIII)** (*1133*).

The major toxicities of IFN-alfa (pegylated or standard) include influenza-like symptoms (e.g., fever, myalgia, headache, and fatigue), neuropsychiatric abnormalities (e.g., depression, irritability, and cognitive dysfunction), cytopenias (e.g., thrombocytopenia and neutropenia, including a reversible reduction in $CD4^+$ count), retinopathy, neuropathy, and exacerbation of autoimmune disease. Depression might be severe enough to trigger suicide. Depending on the severity of these toxicities and individual patient tolerance, side effects might be dose limiting or interfere with the ability to complete a course of treatment.

The major toxicities of RBV include dose-dependent hemolytic anemia, cough, and dyspepsia. RBV potentiates the intracellular activity of didanosine through inhibition of inosine monophosphate dehydrogenase. Because the interaction of RBV and didanosine might lead to clinically significant inhibition of mitochondrial DNA polymerase gamma, resulting in severe pancreatitis, lactic acidosis and, in some patients, death, the combination of RBV and didanosine is strictly contraindicated **(EI)** (*1134*). Zidovudine can potentiate RBV-related anemia, and if other ARVs are available, modification of the ART regimen to remove zidovudine is recommended before treatment for HCV infection **(BII)** (*1135*). Persons in whom the discontinuation of zidovudine is not feasible should be monitored closely (every 2 weeks) for the new onset of severe anemia during the first 8 weeks of treatment. Studies support the use of erythropoietin for the management of clinically significant anemia during HCV treatment. The use of epoetin alfa might permit RBV doses to be optimized and has been associated with improved quality of life (*1136*).

Mental health should be evaluated before initiation of therapy for HCV infection and should be monitored at regular intervals during treatment. Certain specialists recommend the use of standardized depression screening tools such as the Center for Epidemiologic Studies Depression Scale (CES-D). Adverse neuropsychiatric effects of pegIFN-alfa and RBV might be modified by the use of adjunctive agents such as antidepressants.

As with HBV coinfection, in HCV-coinfected persons, IRIS might be manifested by dramatic increases in serum aminotransferases as $CD4^+$ counts rise within the first 6–12 weeks after starting ART. The signs and symptoms are characteristic of hepatitis flares. After introduction of ART, serum aminotransferases should be monitored closely; some experts recommend monthly for the first 3–6 months and then every 3 months thereafter. Any association between abnormal aminotransferases and clinical jaundice or synthetic dysfunction (elevated INR) should prompt consultation with a hepatologist.

In this setting, distinguishing hepatotoxicity or other causes of hepatitis (acute HAV or acute HBV infections) from IRIS is difficult. All classes of ARVs have been associated with hepatotoxicity, which might be dose-dependent or idiosyncratic. The risk for hepatotoxicity has been consistently associated with elevated pre-ART aminotransferases and the presence of HBV or HCV coinfection (*1065-1067,1069–1073,1137*). Despite the increased risk for hepatotoxicity in the setting of HCV or HBV coinfection, the majority of (80%–90%) coinfected patients do not develop hepatotoxicity (*1067*), and clinically significant hepatotoxicity is rare; aminotransferases return to baseline in the majority of cases, even if the offending medication is continued (*1066,1074*). Therefore, discontinuing treatment in the presence of hepatotoxicity is probably not necessary unless the patient has symptoms of hypersensitivity (fever, lymphadenopathy, rash), symptomatic hepatitis (nausea, vomiting, abdominal pain, or jaundice), or elevations of serum aminotransferase levels >10 times the ULN. The development of jaundice is associated with severe morbidity and mortality and should trigger discontinuation of the offending drug(s) (*1075*). No reliable clinical or laboratory parameter is available that will distinguish hepatotoxicity from IRIS. Similarly, liver biopsy might not be diagnostic and are not recommended except in the presence of hepatotoxicity grade 4 or fulminant hepatitis. Prospective studies are evaluating the incidence of presumptive IRIS within the first 12 months of ART initiation. No studies exist to inform the optimal management of persons who experience IRIS in this setting.

Management of Treatment Failure

No data are available on which to base recommendations for treatment of HIV/HCV coinfected patients who fail to respond to initial treatment for HCV infection. Certain patients might benefit from retreatment with interferon-based regimens depending on their previous response, tolerance, and adherence to and the type of previous therapy, the potential potency of the new treatment regimen, the severity of liver disease, viral genotype, and other underlying factors that influence response. On the basis of limited data in persons with HCV monoinfection, extension of the duration of treatment with pegIFN plus RBV might enhance SVR rates in coinfected persons who experience a virologic response to HCV treatment followed by relapse after adequate therapy. For persons with advanced fibrosis (e.g., bridging fibrosis or cirrhosis) and for HIV/HCV-coinfected persons who fail to demonstrate an EVR

on a pegIFN and weight-based RBV regimen, clinical trials indicate that maintenance pegIFN therapy is not associated with decreased risk for hepatic events or with slowing of liver fibrosis progression in HIV-infected and -uninfected persons (*1138*). Therefore, maintenance pegIFN therapy is not recommended **(AI)**.

Preventing Recurrence

For HIV/HCV coinfected patients, treatment-induced SVR appears to be durable and low rates of recurrent viremia have been observed in persons with undetectable HCV RNA >1 year after completion of therapy (*1133*). Persons with HIV infection who achieve SVR should be counseled to stop using injection drugs, and those who continue to inject drugs should be counseled to use safe injection practices to prevent reinfection. Use of barrier precautions and other methods to prevent sexual transmission of HIV should be adequate to prevent reinfection with HCV via sexual practices.

Special Considerations During Pregnancy

Pregnant HIV-infected women should be tested for HCV infection to allow appropriate management during pregnancy and following delivery, and for their infants after birth (*1139*). The treatment of chronic hepatitis C during pregnancy is contraindicated **(EIII)**. Both peginterferon and RBV are contraindicated in pregnancy. Although interferons are not teratogenic, they are abortifacient at high doses in monkeys and should not be used in pregnant women because of the direct antigrowth and antiproliferative effects of these agents (*1087*).

RBV is an FDA category X drug because of its teratogenicity at low doses in multiple animal species. Defects noted in animals include limb abnormalities, craniofacial defects, exencephaly, and anophthalmia. RBV should not be used during pregnancy **(EIII)**. Women of childbearing potential and men receiving RBV should be counseled about the risks and need for consistent contraceptive use during and for 6 months after completion of RBV therapy. However, inadvertent pregnancy during paternal exposure has not been associated with adverse events (*1140*). Pregnancies that occur in women taking RBV should be reported to the Ribavirin Pregnancy Registry (800-593-2214 or http://www.ribavirinpregnancyregistry.com).

Evaluation of HCV-infected pregnant women, including liver biopsy, can be delayed until >3 months after delivery to allow potential pregnancy-related changes in disease activity to resolve. Hepatitis A and hepatitis B vaccination can be administered during pregnancy.

Elective Cesarean delivery does not appear to reduce the risk for HCV transmission from mother to child in HIV-uninfected women, but might be protective against transmission of HCV among HIV-infected women (*1089,1141*). The adjusted odds for perinatal transmission of HCV with scheduled Cesarean delivery among HIV-infected, HCV-seropositive women was 0.36 (0.2–0.8) compared with other modes of delivery. However, another study was unable to confirm the protective effect of Cesarean delivery, possibly because two thirds of the women with HIV/HCV coinfection received an elective Cesarean delivery (*1142*). Although elective Cesarean delivery in HIV/HCV-coinfected women might be considered based on HIV-related indications, data are insufficient to support its routine use for prevention of HCV transmission **(DIII)**.

Infants born to HIV/HCV-coinfected women should be tested for HCV RNA at 2 and 6 months and for HCV antibody after 15 months of age **(CIII)**.

Progressive Multifocal Leukoencephalopathy/JC Virus Infection

Epidemiology

Progressive multifocal leukoencephalopathy (PML) is an OI of the CNS, caused by the polyoma virus JC virus (JCV) and characterized by focal demyelination (*1143*). The virus has worldwide distribution and approximately 85% of adults are seropositive for JCV (*1144*). Primary JCV infection usually occurs in childhood but is not accompanied by any identified symptoms. However, infection likely results in a chronic asymptomatic carrier state in most persons, explaining frequent virus detection in urine (30%) and tonsils (40%) of immunologically normal adults (*1145–1150*). Outside of the context of HIV infection, PML is rare and usually manifests as a complication of other diseases or therapies accompanied by compromised immunity (*1151,1152*). Interest in PML has increased outside of the HIV context as a result of three cases that developed in patients with multiple sclerosis and regional enteritis after treatment with natalizumab, a therapeutic antibody directed against alpha-4 integrins (*1153–1156*). More recently, two patients with SLE receiving rituximab, a therapeutic antibody directed at the B-cell antigen CD20, acquired PML (http://www.fda.gov/cder/drug/advisory/rituximab.htm). This event raises a cautionary note regarding monitoring PML risk when treating non-Hodgkin's lymphoma with rituximab in HIV-infected patients (*1157,1158*). However, no reports have documented PML associated with use of rituximab in HIV infection.

Before the advent of potent combination ART, PML eventually occurred in 3%–7% of AIDS patients (*1159–1161*) and was almost invariably fatal, with only rare spontaneous remission (*1162*). After the widespread use of combination ART in the developed world, the incidence of PML has decreased substantially (*1163*). However, morbidity and mortality associated with PML in HIV-infected patients remains high

(*1164*). Unlike some of the other CNS OIs that are almost wholly prevented when $CD4^+$ counts are maintained above 100–200 cells/μL, PML might still appear in such patients and in those on ART (*1165,1166*). Moreover, PML might develop in the setting of initiating ART and immune reconstitution (*1166,1167*).

Clinical Manifestations

PML manifests as focal neurological deficits, usually with insidious onset and steady progression. Because the demyelinating lesions might involve different brain regions, the specific deficits vary from patient to patient. Any region of the CNS might be involved, but some areas seem to be more favored, including the occipital lobes (with hemianopia), frontal and parietal lobes (hemiparesis and hemisensory deficits), and cerebellar peduncles and deep white matter (dysmetria and ataxia). Spinal cord involvement appears rare (*1168*). Although lesions can be multiple, often one predominates clinically. Additionally, because the individual lesions expand concentrically or along white matter tracts, initial symptoms and signs often begin as "partial" deficits (e.g., weakness of one leg) that worsen and involve a larger territory (e.g., evolution to hemiparesis). The focal or multifocal nature of the pathology is responsible for the consistency of clinical presentations with distinct focal symptoms and signs rather than as a more diffuse encephalopathy or dementia, which is rare (*1169*).

The time course of this evolving demyelination, with clinical progression during several weeks, often provides a clue to diagnosis, because the other major opportunistic focal brain disorders (cerebral toxoplasmosis and primary CNS lymphoma) characteristically progress more rapidly in hours or a few days, and cerebral infarcts begin even more abruptly. Headache and fever are not part of the disease, but seizures develop in nearly 20% of PML patients and are associated with PML lesions immediately adjacent to the cortex (*1170*).

Diagnosis

The initial recognition of PML relies on a combination of clinical and neuroimaging findings. The first step is usually identifying the clinical picture of steady progression of focal neurological deficits. The MRI almost always confirms distinct white matter lesions in areas of the brain corresponding to the clinical deficits. The lesions are usually hyperintense (white) on T2-weighted and fluid attenuated inversion recovery sequences, and also characteristically hypointense (dark) on T1-weighted sequences. The latter might be subtle but helps to distinguish the PML lesion from other pathologies, including the white matter lesions of HIV encephalitis. In contrast to cerebral toxoplasmosis and primary CNS lymphoma, no mass effect or displacement of normal structures is usually evident. Although contrast enhancement is present in 10%–15% of cases, it is usually sparse, with a thin or reticulated appearance adjacent to the edge of the lesions. Exceptions to these characteristic imaging findings might be noted when the inflammatory form of PML develops in the setting of immune reconstitution after initiation of ART.

In most cases, clinical picture and imaging findings support a confident presumptive diagnosis of PML. However, confirming the presence of JCV as the cause is often an advantage. This is invaluable in atypical cases, and even in the more typical setting, helps physicians to proceed rapidly and with certainty in therapy, preventing the need to revisit diagnosis when disease progression continues. The first approach to etiological diagnosis uses PCR to identify JCV DNA in CSF obtained by lumbar puncture. This is positive in approximately 70%–90% of patients not taking ART, and a positive result can be taken as diagnostic in this clinical context (*197,1148*). In patients not on ART, the number of JCV DNA copies can add additional information for prognosis, although this does not seem to hold for those on ART (*1171,1172*). CSF analysis may be repeated if JCV PCR is negative but suspicion remains high, and alternative diagnoses (e.g., focal VZV or primary CNS lymphoma) also are not supported by negative VZV and EBV PCR analysis. When these practices fail, brain biopsy may be undertaken unless otherwise contraindicated. PML can usually be identified by the characteristic tissue cytopathology, including oligodendrocytes with intranuclear inclusions, bizarre astrocytes, and lipid-laden macrophages, whereas JCV infection is confirmed by immunohistochemistry, in situ nucleic acid hybridization, or electron microscopy (*1151,1173,1174*). Because PML develops as a result of endogenous infection and high seroprevalence of JCV infection, blood serology is not useful in diagnosis.

PML developing in the setting of immune reconstitution related to ART warrants special consideration and presents some differences from classical PML. PML has been reported to occur within the first weeks to months after initiating ART in certain patients (*1166,1167*). Additionally, some patients exhibit atypical features that include mass effect of the PML lesions with surrounding edema and on occasion, striking contrast enhancement on MRI. This presentation has been referred to as inflammatory PML or IRIS PML. Histopathology might demonstrate perivascular mononuclear inflammatory infiltration (*1175–1178*). In addition, the likelihood of detecting JCV in CSF might be reduced in these patients compared with classic PML, although this needs further study (*1179,1180*). These cases are presumed to represent the confluence of subclinical CNS JCV infection and restoration of immune responses to JCV by ART with resultant local immune and inflammatory

responses, but other undefined factors might affect PML development in this setting.

Preventing Exposure

JCV has a worldwide distribution and most persons exhibit serologic evidence of exposure by their late teens. No known way exists to prevent exposure to the virus.

Preventing Disease

JCV likely continues as a silent productive infection in the kidney in many persons, and this might increase in the presence of immunosuppression. Whether JCV is latent in the CNS or whether PML results from temporally more proximate hematogenous dissemination in those who have this disease is unknown. Protection is presumably conferred by active, effective immunosurveillance. Therefore, the only effective way to prevent disease is to prevent progressive HIV-related immunosuppression with ART **(AIII)**.

Treatment of Disease

No established specific therapy exists for JCV infection or PML, and the main approach to treatment involves ART to reverse the immunosuppression that interferes with the normal host response to this virus. Treatment strategies depend on the patient's antiretroviral treatment status and its effect. Thus, in patients who have PML and who are not on therapy, ART should be started immediately **(AII)**. For patients with PML who remain HIV-viremic because of antiretroviral resistance, their ART regimen should be optimized for virologic suppression **(AIII)**. More problematic are patients who have PML despite successful virologic suppression while taking HAART. A recent report of patients who were treated intensively with four classes of ART (including enfuvirtide) suggested that this strategy might offer higher than anticipated survival (*1181*). The effectiveness of an ART-intensification strategy in patients with undetectable plasma HIV requires further study **(CIII)**. Approximately half of patients with PML in the setting of HIV infection experience a remission after initiating effective ART (*1179,1182–1189*). Although their neurological deficits frequently persist, disease progression in these patients remits. Some also will experience a degree of functional improvement. In one retrospective study, including 118 consecutive patients with PML, 75 patients (63.6%) remained alive for a median of 114 weeks (2.2 years) after diagnosis of PML (*1189*). Neurological function of the survivors was categorized as cure or improvement in 33, stabilization or worsening in 40, and unknown in 2. In this study the $CD4^+$ count at presentation was the only variable that predicted survival; the odds ratio for death among patients with $CD4^+$ counts <100 cells/μL compared with patients who had higher $CD4^+$ counts was 2.71. According to some case series, prognosis also depends on whether patients are not on therapy at the time of presentation (and thus whether treatment can be improved), plasma HIV RNA levels, and virologic responses to treatment (*1166,1179,1185,1188–1190*). Contrast enhancement on imaging also might predict better outcome (*1165*).

Several agents have been proposed or reported anecdotally as more specific treatments for PML, but none of these has proven effective after more intensive scrutiny or more extensive study. On the basis of earlier case reports and drug inhibition of JCV in cell culture, IV and intrathecal cytaribine (cytosine arabinoside) were tested in a clinical trial, but neither exhibited clinical benefit (*1191*). Therefore, treatment with cytarabine is not recommended **(DI)**. Although cidofovir is not effective against JCV in cell culture (*1192*), initial case reports and retrospective series described efficacy in HIV-infected and uninfected patients with PML (*1186*). However, subsequent reports, including retrospective case-control studies (*1187,1189,1193*), an open-label study of cidofovir in HIV-infected PML patients (*1188*) and, eventually, a meta-analysis including the patients from the four above studies (*1194*) demonstrated no neurological benefit. Thus, treatment with cidofovir is not recommended **(DII)**.

Immunomodulatory approaches for treatment of PML also have been tried, but none has yet been studied in a prospective, controlled clinical trial. Although an initial retrospective analysis suggested that interferon-alpha might improve survival of HIV-infected patients with PML (*1195*), a subsequent retrospective analysis did not demonstrate benefit beyond that afforded by ART; therefore, interferon-alpha cannot be recommended **(DIII)** (*1196*)**.** A single report described failure of interferon-beta treatment of HIV-associated PML (*1197*). Case reports describe improvement in PML-related neurological dysfunction or recovery in three non-HIV-infected patients who underwent transplantation for lymphoma and in one patient with myelodysplastic syndrome treated with interleukin-2 (*1198–1200*). After a cell-culture study that indicated JCV replication could be inhibited by a topoisomerase inhibitor (*1201*), an analogue, topotecan, was studied in a small trial. Results suggested a salutary effect in some, although likely little different from the natural course in other AIDS patients; therefore, topotecan is not recommended **(DIII)** (*1202*).

On the basis of a report indicating that the serotonergic 5HT2a receptor can serve as the cellular receptor for JCV in a glial cell culture system (*1203*), drugs that block the 5HT2a receptor, including olanzapine, zisprasidone, mirtazapine, cyproheptadine, and risperidone, have been suggested as treatment for PML (*1204*), although the rationale for this practice has been questioned (*1205*). Although anecdotal reports of using 5HT2a receptor inhibitors are available

(*1143,1206–1208*), previous disappointments after case reports of "successful" treatment emphasize the need to test this strategy by formal trial. Therefore, routine use of these agents is not justified **(CIII)**.

Because ART-induced immune reconstitution is associated with both onset and paradoxical worsening of PML, corticosteroids have also been advocated and sometimes empirically used—at varying dosages and durations—in the treatment of PML. This approach has been extended by some to include all cases of PML, including those with little or no demonstrable inflammatory component. However, no evidence supports the routine use of corticosteroids in HIV-related PML without an inflammatory response on neuroimaging **(DIII)**. In patients with inflammatory PML, corticosteroid treatment might have a more rational basis.

Monitoring and Adverse Events, Including Immune Reconstitution Inflammatory Syndrome (IRIS)

Because the main approach to PML treatment is to reverse immunosuppression, patients might experience an exuberant response that can be classified as an IRIS or immune restoration disease (IRD) (*298*). Because restoration of anti-JCV defenses is the objective of ART treatment in PML patients, the salutary therapeutic response and the immunopathology of IRIS might intersect and overlap in the same patient. The concern in these patients is to determine when the immune or inflammatory response is helpful and when harmful by virtue of local bystander cytotoxicity and edema that cause further injury and threaten brain displacement and herniation. The cellular immune response against JCV, mediated by $CD8^+$ T-lymphocytes, is critical to the containment of PML progression and has been associated with a favorable clinical outcome (*1209*).

However, an "excessive" response related to IRIS might be lethal as a consequence of the inflammatory reaction or, rarely, brain swelling and herniation (*1210*). This inflammatory PML might be the disease phenotype on initial examination in patients who have recently begun ART or might evolve after ART has been initiated in the context of PML treatment. Corticosteroids have been used to control the local inflammatory reaction and reduce associated cerebral edema in this setting. Little published information exists to support their efficacy or, more specifically, to guide dosage and duration of this treatment. Corticosteroid treatment should be as short as possible and not overused. Mild swelling, edema, or contrast enhancement might be noted in some patients who respond favorably to ART, but most often these complications require no additional treatment if the patient is clinically stable and has no sign of impending brain herniation. However, in those with progressing clinical deficits and neuoroimaging features suggesting inflammatory disease (edema, swelling, and contrast enhancement), corticosteroid treatment is justified **(BIII)**. Although some have suggested stopping ART in the face of PML-IRIS, this is likely counterproductive and is not recommended **(DIII)**.

Management of Treatment Failure

Because PML remission might take several weeks, no strict criteria define disease progression. However, a working definition might be continued clinical worsening and continued detection of CSF JCV at 3 months. In the case of ART treatment, the plasma HIV RNA and blood $CD4^+$ count responses might provide ancillary predictive information. When the suppression of HIV RNA or the boost of $CD4^+$ count fails, attention might focus on modifying ART. Augmenting ART even when plasma HIV RNA is below detection is under study. However, when HIV responds well to ART but PML continues to worsen, attempting one of the unproven and not routinely recommended therapies described above is reasonable, after all are informed of their rationale and unproven efficacy. Better treatments and their rigorous assessment are needed.

Preventing Recurrence

Patients experiencing remission of PML after ART rarely suffer a subsequent recrudescence (*1187*), although no formal study of this has been undertaken. The main preventive measure, based on its role in reversing the disease, is an effective ART regimen that suppresses viremia and maintains $CD4^+$ counts **(AII)**.

Special Considerations During Pregnancy

Diagnostic evaluation for PML should be the same in pregnant women as in nonpregnant women. Therapy during pregnancy should consist of optimizing the antiretroviral regimen.

Geographic OIs of Specific Consideration

Malaria

Plasmodium falciparum malaria and HIV both cause substantial morbidity and mortality, particularly in sub-Saharan Africa. Given this substantial overlap, even modest interactions between them have public health importance. Early studies failed to identify important interactions between malaria and HIV (*1211,1212*). However, more recent evidence supports the presence of the effect of each infection on the other (*1213*).

Epidemiology

P. falciparum, *P. vivax*, *P. ovale*, and *P. malariae*, and a recently described species in humans, *P. knowlesi*, differ in geographic distribution, microscopic appearance, and clinical features. Although *P. vivax* infections are more common, worldwide, *P. falciparum* malaria represents the most serious public health problem because of its tendency toward severe or fatal infections.

Malaria is typically transmitted by the bite of an infected female *Anopheles sp*. mosquito. Nonmosquito-borne routes of infection (congenital, transfusion) occur less frequently (*1214–1216*).

Malaria transmission has occurred in 107 countries and territories worldwide (*1217*). Thirty-six percent of the global population lives in areas in which a risk for malaria transmission occurs (*1218*). Each year an estimated 300–500 million clinical cases of malaria occur, making it one of the most prevalent infectious diseases (*1219*). Approximately 80% of the approximately 1 million deaths attributed to malaria each year occur among African children (*1217*).

The clinical syndromes caused by malaria depend on whether a patient comes from an area with stable endemic malaria transmission or unstable (infrequent or very low) transmission (*1220*). In stable endemic areas, young children (<5 years) might experience chronic infections with recurrent parasitemia, resulting in severe anemia and often death. Those who survive repeated infections acquire partial immunity by age 5 years and, if they remain in the area where malaria is endemic, maintain this immunity into adulthood. Adults in stable endemic areas usually experience asymptomatic or milder infections. In unstable transmission areas, immunity is not acquired. In these areas, the overwhelming clinical manifestation is acute febrile disease that can be accompanied by cerebral malaria, affecting persons of all ages.

Pregnant women in areas of unstable transmission might experience acute malaria, spontaneous abortion, and stillbirth. In more stable transmission areas, pregnant women might lose some acquired immunity. Although infections might be asymptomatic, women acquire placental malaria that contributes to intrauterine growth retardation, low birthweight, and the concomitant risk for increased infant mortality.

HIV impact on malaria

Parasitemia and clinical severity. HIV disease impairs the acquired immunity to malaria evident in older children and adults in endemic areas. Large cohort studies have demonstrated evidence of increased frequency (with rates one- to twofold higher) of both parasitemia and clinical malaria in HIV-infected adults, with increasing risk and higher density parasitemia associated with more advanced immunosuppression (*1221,1222*). The rates of increased malaria among persons with HIV are not as great as observed with classic OIs like TB and PCP (*1223*).

In a prospective cohort study in an area with unstable malaria transmission, HIV-infected nonimmune adults were at increased risk for severe malaria, and the risk was associated with a low $CD4^+$ count (*1224*). Nonimmune HIV-infected patients were substantially more likely to have severe clinical malaria than were nonimmune patients without HIV. In another area of unstable malaria transmission, HIV-infected adults hospitalized for malaria were substantially more likely to die or require an ICU admission than those without HIV (*1225*). In contrast, HIV infection did not confer an increased risk for these severity measures among partially immune adults from areas with more stable transmission (*1221*).

The situation is more complex in children. Early studies among HIV-infected infants did not suggest an increase in frequency or density of parasitemia associated with HIV infection (*1226,1227*). More recent data suggest increased rates of parasitemia and higher densities among somewhat older HIV-infected children (up to age 5 years) compared with those without HIV (*1228*). As with adults, older children with HIV might be at increased risk for clinical malaria because of HIV-induced impairment of acquired anti-malarial immunity. HIV-infected infants in Kenya were at increased risk for severe anemia and for hospitalization because of malaria (*1229*). Limited data from areas in which malaria is not endemic also suggest HIV is associated with more severe malaria in older children (*1230*).

Malaria treatment outcomes. Prospective clinical trial data from Kenya indicated that among adults with uncomplicated malaria treated with sulfadoxine-pyrimethamine (SP), the risk for failure 28 days post treatment was substantially higher among HIV-infected adults with low $CD4^+$ counts (<200 cells/uL) than in the HIV-uninfected group (*1231*). In multivariable analysis, the combination of HIV infection with $CD4^+$ count <200 cells/uL and anemia was the only substantial risk factor for treatment failure at 28 days. Similar results were observed in Zambian adults with uncomplicated malaria (*1232*). Widespread resistance to SP has prompted certain countries to adopt policies calling for use of artemisinin-containing combination therapies (ACTs) for first-line treatment for malaria. Assessing whether HIV-related immunosuppression adversely affects efficacy of ACTs in malaria treatment is important.

Malaria Effect on HIV

Viral load and transmission. As occurs with TB and other major OIs, malarial episodes are associated with increased HIV viral load (*24*). Modeling studies have suggested that this increase could affect HIV transmission (*25*). In preg-

nant women, recent studies have also confirmed that malaria parasitemia was associated with increased HIV concentrations, with a magnitude similar to that observed in asymptomatically infected nonpregnant adults (*1233*).

Mother-to-child HIV transmission. Placental malaria also has been associated with increased expression of CCR5 receptors in placental macrophages (*1234*) and increased viral load (*1235*), raising the possibility of placental malaria leading to increased MTCT of HIV. However, data concerning the effect of malaria during pregnancy on the risk for MTCT of HIV are conflicting. One study in Uganda demonstrated increased MTCT in women with placental malaria (*1236*), but studies from Kenya did not demonstrate this association (*1237,1238*).

Blood transfusion transmission. Because anemia caused by *P. falciparum* remains a frequent indication for blood transfusions, malarial anemia can have an important indirect effect on the risk for HIV transmission (*1239*). Improved blood collection and testing practices are leading to improved transfusion safety in Africa (*1240,1241*), but few countries conduct universal screening of blood.

Clinical Manifestations

Patients with malaria can exhibit various symptoms and a broad spectrum of severity depending upon such factors as the infecting species and level of acquired immunity in the host. As noted previously, HIV-immunosuppressed persons in endemic areas might lose acquired malarial immunity, and HIV-immunosuppressed adults with little or no previous malaria exposure such as travelers might be at increased risk for severe outcomes (*1242*).

Among nonimmune persons, typical symptoms of malaria include fever, chills, myalgias and arthralgias, headache, diarrhea, vomiting, and other nonspecific signs. Splenomegaly, anemia, thrombocytopenia, pulmonary or renal dysfunction, and neurologic findings also might be present. Classically, paroxysmal fevers occur every 48 hours for *P. falciparum*, *P. vivax*, and *P. ovale* malaria; those of *P. malariae* occur every 72 hours. However, this classic presentation is highly variable and might not be present.

Uncomplicated malaria infection can progress to severe disease or death within hours. Malaria with CNS symptoms can be particularly ominous. Cerebral malaria refers to unarousable coma not attributable to any other cause in a patient infected with *P. falciparum*; in Africa, case fatality rates with cerebral malaria might approach 40% (*1243–1245*). The risk for severe and complicated illness is increased in patients with high levels of parasitemia and without partial immunity. Metabolic acidosis appears to be an important manifestation of severe malaria and indicator of poor prognosis (*1246*). Other acute complications include renal failure, hypoglycemia, disseminated intravascular coagulation, shock, and acute pulmonary edema (*1247*). *P. falciparum* is the species responsible for severe disease and death; severe or fatal malaria rarely results from infections with the other species. A rare exception is spleen rupture, which can occur with acute nonfalciparum malaria (*1248*).

Diagnosis

The diagnosis of malaria must be considered in all febrile patients who have traveled to or lived in malaria-endemic areas or who have received blood products, tissues, or organs from persons who have been to such areas. Several diagnostic methods are available, including microscopic diagnosis, antigen detection tests, PCR-based assays, and serologic tests. Direct microscopic examination of intracellular parasites on stained blood films is the standard for definitive diagnosis in nearly all settings. In nonimmune persons, symptoms might develop before detectable levels of parasitemia are evident. For this reason, several blood smear examinations taken at 12–24-hour intervals might be needed to positively rule out a diagnosis of malaria in a symptomatic patient. Guidelines for laboratory diagnosis are summarized elsewhere and are available at CDC's malaria website (http://www.cdc.gov/malaria/).

Preventing Exposure

Infection with *P. falciparum* in HIV-infected persons with low $CD4^+$ counts and in pregnant women regardless of HIV infection status can be more severe than in other persons. Because no chemoprophylactic regimen is completely effective, HIV-infected persons with low $CD4^+$ counts and women who are pregnant or likely to become pregnant should be advised to avoid travel to areas with malaria transmission if possible **(AIII)**. If travel to a malarious area cannot be deferred, use of an effective chemoprophylaxis regimen is essential, along with careful attention to personal protective measures to prevent mosquito bites.

Preventing Disease

In areas where malaria is endemic, strategies to prevent malaria and its consequences include vector control, prophylaxis, and intermittent preventive treatment in pregnancy. For U.S. travelers (including HIV-infected persons) to malarious areas, a combination of chemoprophylaxis and personal protective measures can be highly effective in preventing malaria. One of three drugs is recommended for prophylaxis: atovaquone-proguanil, mefloquine, or doxycycline. Recommendations for prophylaxis are the same for HIV-infected persons as for noninfected persons and are available at CDC's malaria website **(AIII)** (http://www.cdc.gov/malaria). Malaria incidence has been markedly reduced in African adults with HIV who

receive cotrimoxazole (TMP-SMX) prophylaxis (*30,1249*). A recent study of HIV-infected persons in Uganda demonstrated that malaria burden was reduced by 70% with cotrimoxazole, was then reduced a further 50% when antiretroviral drugs were provided, and finally a further 50% with provision of insecticide-treated nets (*1250*). However, cotrimoxazole is not as effective an antimalarial prophylactic regimen as the antimalarials recommended (Table 2). Therefore, HIV-infected travelers on prophylaxis with cotrimoxazole should not rely on it for chemoprophylaxis against malaria **(AIII)**.

Treatment of Disease

Because *falciparum* malaria can progress within hours to severe disease or death, all HIV-infected persons with confirmed or suspected *P. falciparum* infections should be admitted to the hospital for evaluation, initiation of treatment, and observation of response to treatment. Ideally, antimalarial treatment should not be initiated until the diagnosis has been confirmed by laboratory investigations. However, treatment should not be delayed when malaria is strongly suspected but laboratory results are pending.

The choice of treatment is guided by the degree of parasitemia and the species of *Plasmodium* identified, the clinical status of the patient, and the likely drug susceptibility of the infecting species as determined by where the infection was acquired. Although impaired response has been noted in HIV-immunosuppressed persons treated with older antimalarials such as sulfadoxine pyrimethamine (*1231,1232*), no evidence indicates that response in these persons is impaired if currently recommended drugs are used. Therefore, for HIV-infected patients who do acquire *Plasmodium* infection, treatment recommendations are the same as for HIV-uninfected patients **(AIII)**. Detailed antimalarial treatment recommendations have been reviewed recently (*1251*). CDC posts current treatment recommendations on its website (http://www.cdc.gov/malaria) and has clinicians on call 24 hours to provide advice to clinicians on the diagnosis and treatment of malaria (CDC Malaria Hotline 770-488-7788 M–F 8 AM–4:30 PM ET, 770-488-7100 after hours).

Monitoring and Adverse Events, Including Immune Reconstitution Inflammatory Syndrome (IRIS)

Several potential drug interactions can occur between antimalarial and HIV drugs, and these have been reviewed recently (*1252*). Atovaquone and doxycycline interactions with antiretroviral drugs and with drugs used to prevent and treat OIs have been summarized previously (*37,1253*). Mefloquine in repeated doses has been observed to reduce area under the concentration-time curve and maximal plasma concentrations of ritonavir by 31% and 36%, respectively. Sufficient data are not available to suggest that dose adjustments are needed.

Quinine levels might be increased by ritonavir-containing regimens; conversely, nevirapine and efavirenz could reduce plasma quinine levels. Potential interactions can occur between ritonavir with chloroquine; however, the clinical significance of these interactions is unclear and until further data are available, no dose adjustments are recommended. Artemisinin-containing compounds such as artesunate, which are widely used for antimalarial treatment in other parts of the world, are not yet approved in the United States. However, artesunate might soon be available for treatment of severe malaria in the United States through a compassionate use Investigational New Drug application. PIs and NNRTIs have the potential to affect metabolism of artemisinin-containing drugs (*1254*), but the overall effect and clinical significance remain unclear. No IRIS has been described in association with malaria.

Management of Treatment Failure

Management of treatment failure for persons with HIV infection should not differ from HIV-positive patients except in terms of drug interactions and drug toxicities as noted above.

Prevention of Recurrence

Not Applicable.

Special Considerations During Pregnancy

Malaria in pregnancy affects both the mother and the fetus. Infection with *P. falciparum* during pregnancy can increase the mother's risk for having severe disease and anemia and increase the risk for stillbirth, preterm birth, and low birthweight (*1255*). The diagnosis of malaria in pregnant women is the same as in nonpregnant women.

For pregnant women with a diagnosis of uncomplicated malaria caused by *P. malariae*, *P. ovale*, chloroquine-sensitive *P. vivax*, and chloroquine-sensitive *P. falciparum*, prompt treatment with chloroquine is recommended (*1251*). For pregnant women with a diagnosis of chloroquine-resistant *P. vivax*, treatment with quinine for 7 days is recommended (**AIII**). For pregnant women with a diagnosis of uncomplicated chloroquine-resistant *P. falciparum* malaria, prompt treatment with quinine and clindamycin is recommended.

On the basis of extensive experience with its use, chloroquine is considered the drug of choice for prophylaxis and treatment of sensitive strains of malaria in pregnancy. Although quinine at high doses has been associated with an increased risk for birth defects (especially deafness) in some animal species and humans (usually during attempted abortion), use of therapeutic doses in pregnancy is considered safe (*1251,1256*). Because of the potential for hypoglycemia, pregnant women treated

with quinine and their neonates should have monitoring of glucose levels. Clindamycin use has not been associated with birth defects. Because of limited data, atovaquone-proquanil or mefloquine are not recommended for treatment in pregnancy and should be used only if quinine plus clindamycin or quinine monotherapy is not available or not tolerated (*1256*). Animal data and human data on use of prophylactic doses of mefloquine do not suggest teratogenicity. Tetracyclines are not recommended in pregnancy because of increased risk for maternal hepatotoxicity and staining of fetal teeth and bones. Primaquine use during pregnancy is not recommended because of limited experience with its use and the potential for fetal G6PD deficiency. Artesunates are not available in the United States.

After treatment, all pregnant women with *P. vivax* and *P. ovale* should be administered chloroquine prophylaxis for the duration of the pregnancy to avoid relapses. For pregnant women with *P. vivax* acquired in an area with chloroquine-resistant strains, once-weekly mefloquine can be used for prophylaxis. Women can be treated with primaquine after delivery if they have a normal G6PD screening test.

Penicilliosis marneffei

Epidemiology

Penicilliosis marneffei (penicilliosis) is caused by the dimorphic fungus *Penicillium marneffei*, which is endemic in Southeast Asia (especially Northern Thailand) and southern China (*1257–1259*). More recently, 50 indigenous cases of penicilliosis occurred in Manipur State, India, a new endemic area of this fungus (*1260,1261*). International travel requires increased awareness and recogntion of penicilliosis and its treatment.

Before the antiretroviral treatment era, penicilliosis was the presenting AIDS-defining illness in 6.8% of HIV-infected patients from the northern provinces of Thailand but less frequently elsewhere (*1262*). The majority of cases of penicilliosis are observed in patients who have $CD4^+$ counts of <100 cells/μL (*1263*). The infection is associated with a high mortality rate if timely treatment with appropriate antifungal drugs is not administered (*1264*).

Clinical Manifestations

The common clinical manifestations include fever, anemia, weight loss, and generalized skin papules with central umbilication resembling molluscum contagiosum (*1257*). Cutaneous penicilliosis lesions commonly appear on the face, ears, extremities, and occasionally the genitalia. Involvement of other organs such as bone marrow, lymph node, lung, liver, and intestine have been reported. Patients with hepatic penicilliosis have fever, abdominal pain, hepatomegaly, and a marked increase in serum alkaline phosphatase levels (*1259*).

Diagnosis

The definitive diagnosis of penicilliosis is based on isolation of organisms from blood culture or other clinical specimens or by histopathologic demonstration of organisms in biopsy material. Fungal cultures at 25ºC (77ºF) demonstrate characteristic features that include a flat green surface and underlying deep red coloring. An early presumptive diagnosis can be made several days before the results of fungal cultures are available by microscopic examination of the Wright-stained samples of skin scrapings, bone marrow aspirate, or lymph-node biopsy specimens. Many intracellular and extracellular basophilic, spherical, oval, and elliptical yeast-like organisms can be seen, some with clear central septation, which is a characteristic feature of *P. marneffei* (*1257*). In some patients, the fungus can be identified by microscopic examination of the Wright's-stained peripheral blood smear (*1265*).

Preventing Exposure

Available information does not support specific recommendations regarding exposure avoidance. However, patients with advanced HIV disease should avoid visiting the disease-endemic areas **(BIII)**.

Preventing Disease

Not applicable to residents of the United States.

Treatment of Disease

P. marneffei is highly susceptible to miconazole, itraconazole, ketoconazole, and 5-flucytosine. Amphotericin B has intermediate antifungal activity, whereas fluconazole is the least active (*1264*). The recommended treatment is amphotericin B in a dose of 0.6 mg/kg body weight/day administered intravenously for 2 weeks, followed by oral itraconazole in a dose of 400 mg/day for a subsequent duration of 10 weeks **(AII)** (*1266*). Patients with mild disease can be initially treated with oral itraconazole 400 mg/day for 8 weeks **(BII)** (*1267*), followed by 200 mg/day for prevention of recurrence. Itraconazole capsule is better absorbed when it is taken with or immediately after a meal. Itraconazole oral solution could be taken on an empty stomach. ART should be administered in accordance with standards of care in the community; consideration should be given to simultaneous administration of treatment for penicilliosis and initiation of ART to improve outcome **(CIII)**.

Monitoring and Adverse Events, Including Immune Reconstitution Inflammatory Syndrome (IRIS)

Patients treated with amphotericin B should be monitored for dose-dependent nephrotoxicity and electrolyte distur-

bances. Preinfusion administration of 500 mL of normal saline appears to reduce the risk for nephrotoxicity during treatment. Infusion-related adverse reactions might be ameliorated by pretreatment with acetaminophen and diphenhydramine; in rare cases, glucocorticosteroids administered approximately 30 minutes before the infusion might be required **(CIII)**.

Because absorption of itraconazole can be erratic, serum itraconazole levels should be obtained once in all patients to ensure adequate absorption **(AIII)**. The serum concentration should be >1 μg/mL, ideally drawn for reasons of consistency as a trough level after at least 7 days on the current regimen. Itraconazole solution is recommended over the capsule formulation because absorption is improved, but this has not been studied specifically in HIV-infected patients.

The immune restoration inflammatory syndrome has been reported uncommonly in patients with penicilliosis (*1268,1269*). It usually occurs within a few weeks or months after starting ART, suggesting a possibility of immune reconstitution unmasking active disease. ART should not be withheld because of concern for the possible development of IRIS **(AIII)**. In patients with severely symptomatic IRIS, short-course glucocorticosteroids are recommended by certain specialists **(BIII)**. Delaying the initiation of potent ART until the end of the first 2 weeks of induction therapy for penicilliosis might be prudent **(CIII)**.

Management of Treatment Failure

Alternative treatment options for penicilliosis are not established. A small case series reported good outcomes with voriconazole (*1270*). For those whose initial therapy has failed, the approach to treatment should consist of reinitiating parenteral amphotericin B followed by another course of oral itraconazole, coupled with optimizing ART, addressing obstacles to adherence, avoiding adverse drug interactions, and ensuring that adequate absorption and serum concentrations of itraconazole are achieved **(AIII)**.

Preventing Recurrence

A study from Chiang Mai University documented that approximately 50% of patients had relapse of penicilliosis marneffei within 6 months after discontinuation of antifungal therapy (*1267,1271*). A double-blind, placebo-controlled study from Chiang Mai, Thailand, demonstrated that oral itraconazole 200 mg daily for secondary prophylaxis in AIDS patients reduced the relapse rate of penicilliosis marneffei from 57% to 0% (p<0.001) (*1271*). All patients who successfully complete treatment for penicilliosis should be administered secondary prophylaxis (chronic maintenance therapy) with oral itraconazole in a dose of 200 mg/day **(AI)**.

Discontinuing Secondary Prophylaxis (Chronic Maintenance Therapy)

No randomized controlled study exists that could demonstrate the safety of discontinuation of secondary prophylaxis for penicilliosis. However, an open-label, historical-controlled trial from Chiang Mai University Hospital indicated that no relapse of penicilliosis and invasive fungal infections occurred after discontinuation of itraconazole in patients receiving ART and $CD4^+$ cell count >100 cells/μL (*1272*). Therefore, discontinuing secondary prophylaxis for penicilliosis is recommended for AIDS patients who receive combination ART and have $CD4^+$ count >100 cells/μL for ≥6 months **(BII)**. Secondary prophylaxis should be reintroduced if the $CD4^+$ count decreases to <100 cells/μL **(AIII)** or if penicilliosis recurs at a $CD4^+$ count of >100 cells/μL **(CIII)**.

Special Considerations During Pregnancy

The diagnosis and treatment of penicilliosis during pregnancy are similar to those in nonpregnant women with the following considerations regarding antifungal use in pregnancy. Because of their risk for teratogenicity, azoles should not be used during the first trimester of pregnancy **(EII)** (See mucocutaneous candidiasis). Neonates born to women on chronic amphotericin B at delivery should be evaluated for renal dysfunction and hypokalemia.

Leishmaniasis

Epidemiology

Leishmaniasis is caused by obligate intracellular protozoa that survive and replicate in intracellular vacuoles within macrophages. The *Leishmania* genus has traditionally been differentiated into multiple species that cause cutaneous, mucosal, or visceral disease *(1273, 1274)*.

Leishmaniasis occurs in 88 countries worldwide with an estimated incidence of 2 million new cases annually *(1275)*.

Leishmaniasis among persons with HIV/AIDS has been reported primarily from Spain, Italy, France, Brazil, and Ethiopia, but most coinfections in the developing world are never reported *(1275)*. The incidence has decreased substantially in developed countries with the introduction of ART *(1276, 1277)*; however, HIV-leishmaniasis coinfection poses a growing problem in Asia and Africa *(1278, 1279)*.

Most infections in immunocompetent hosts are asymptomatic; in some disease-endemic areas, approximately 30% of the population has evidence of latent infection in the form of a positive leishmanin skin test *(1280-1282)*. After primary infection, *Leishmania* remain viable in healthy persons for long periods, leading to a susceptible population if immunosuppression occurs. In HIV-infected persons without severe

immunosuppression, disease manifestations are similar to those in immunocompetent persons. Among those with advanced immunosuppression and low CD4+ counts (<200 cells/μL), manifestations of leishmaniasis might be both atypical and more severe, and relapse after treatment is common *(1283)*.

Leishmaniasis is usually spread by sand flies of the genus *Phlebotomus* or *Lutzomyia (1274)*. However, in Southern Europe, HIV and *Leishmania* coinfections have been reported in association with injection-drug use, suggesting that *Leishmania* also might be acquired by needle sharing *(1284)*. *Leishmania* parasites were demonstrated in 34%–52% of used syringes discarded by IDUs in Madrid, and based on molecular characteristics, investigators have described a new, epidemiologically significant leishmaniasis transmission cycle, relying on mechanical transfer of amastigotes via syringe *(1285, 1286)*.

Clinical Manifestations

Leishmaniasis can occur in four major syndromes: localized cutaneous, diffuse cutaneous, mucosal, and visceral disease. The most common clinical presentation of leishmaniasis in persons with AIDS is a disseminated visceral disease syndrome, but the distribution varies geographically, reflecting differences in the predominant parasite species. In Europe, visceral disease has been reported in 95% of cases (87% typical visceral, 8% atypical visceral) *(1287)*. In contrast, in Brazil, mucocutaneous (43%) and cutaneous (20%) are common *(1288)*.

Among persons with visceral disease, the most common clinical and laboratory findings are fever (65%–100%), systemic malaise (70%–90%), splenomegaly (usually moderate) (60%–90%), hepatomegaly without splenomegaly (34%–85%), hepatosplenomegaly (68%–73%), lymphadenopathy (12%–57%), and pancytopenia (50%–80%)*(1287, 1289)*. Anemia is usually marked with <10g hemoglobin/dL (49%–100%), leukopenia moderate with <2,400 leukocytes/μL (56%–95%), and thrombocytopenia is usually present (52%–93%). Splenomegaly is somewhat less common in HIV-coinfected patients than in immunocompetent patients with visceral leishmaniasis *(1289)*. Among those with more profound immunosuppression, atypical manifestations have been described, including involvement of the upper and lower gastrointestinal tract, lung, pleural and peritoneal cavities, and skin *(1276, 1287, 1289, 1290)*. Esophageal involvement can lead to dysphagia and odynophagia, and must be distinguished from other causes of esophagitis in HIV-infected patients, such as candidiasis *(1287)*. Nonulcerative cutaneous lesions that mimic KS, nodular diffuse leishmaniasis, and post-kala-azar dermal leishmaniasis have been described *(1291)*. However, the presence of *Leishmania* amastigotes in skin might occur in the absence of lesions or in combination with other pathology, such as KS, and might not indicate that the parasite is the cause of the lesions *(1292, 1293)*. Disfiguring mucosal lesions associated with anergy to *Leishmania* antigens have been observed among European persons with AIDS, in contrast to mucocutaneous disease in immunocompetent persons that is associated with strong leishmanin skin-test responses *(1290, 1294, 1295)*.

Diagnosis

Demonstration of characteristic amastigote forms of *Leishmania* by histopathology, cultures, and smears in tissue specimens (e.g., scrapings, aspirates, biopsies) is the standard for diagnosis of cutaneous leishmaniasis among HIV-coinfected patients *(1287)*. The diagnosis of visceral leishmaniasis can also be made by the demonstration of amastigote forms in blood smears (approximately 50% sensitivity in expert hands), buffy-coat smear preparations, cultures from the peripheral blood, and smears or cultures from bone marrow or splenic aspirates. Other methods useful for demonstrating *Leishmania* in the blood or tissue of coinfected patients include detection of *Leishmania* nucleic acid by PCR amplification (>95% sensitivity) *(1296)*.

Antibodies against *Leishmania* antigens are of high sensitive for the diagnostic value among immunocompetent patients with visceral disease (*1297*). However, the sensitivity of serologic tests is substantially lower in HIV-coinfected patients (*1287*, *1298*). The use of recombinant antigen (e.g., rK39) in ELISA assays might increase sensitivity, but a proportion of coinfected patients will remain seronegative (*1299*). Immunoblotting with *Leishmania infantum* soluble antigen has been successful in detecting specific antileishmanial antibodies in up to 70% of European patients (*1298*). Leishmanial skin tests are nearly always negative in active visceral leishmaniasis, with or without HIV coinfection (*1274*).

Preventing Exposure

Primary prevention of leishmanial infection relies on reservoir host control in areas with zoonotic transmission; vector control activities, such as indoor residual spraying and/or insecticide-treated nets; and measures to decrease transmission of infectious agents in IDUs, such as NEPs. For North American residents, these measures are only relevant during travel.

Preventing Disease

Not applicable

Treatment of Disease

Liposomal amphotericin B is the only agent approved by the FDA for the treatment of visceral leishmaniasis *(1300, 1301)*. Pentavalent antimony is the most widely used treatment for leishmaniasis in many parts of the world and remains the

first-line treatment for cutaneous leishmaniasis caused by most species in otherwise healthy patients *(1274, 1302)*.

For HIV-visceral leishmaniasis-coinfected patients, the efficacy of conventional and lipid-associated formulations of amphotericin B appears to be similar to that of pentavalent antimony *(1303-1306)*. However, liposomal and lipid complex preparations are substantially better tolerated than conventional amphotericin B or pentavalent antimony *(1307-1309)*. The equivalent efficacy and better toxicity profile have led most clinicians to regard liposomal amphotericin B as the drug of choice for visceral leishmaniasis in HIV-coinfected patients **(AII)** *(1300)*. The optimal amphotericin B dosage has not been determined *(1300, 1310)*. Regimens with efficacy include conventional amphotericin B 0.5–1.0 mg/kg body weight/day IV to achieve a total dose of 1.5–2.0 grams **(BII)**, or liposomal or lipid complex preparations of 2–4 mg/kg body weight administered on consecutive days or in an interrupted schedule (e.g., 4 mg/kg on Days 1–5, 10, 17, 24, 31, and 38) to achieve a total cumulative dose of 20–60 mg/kg body weight **(BII)** *(1300, 1301, 1303, 1305, 1306, 1311)*. A higher daily dosage is recommended for liposomal or lipid complex (ABLC) preparations than for conventional amphotericin B **(BII)** *(1300, 1301)*.

Few systematic data are available on the efficacy of treatment for cutaneous, mucocutaneous, or diffuse cutaneous leishmaniasis in HIV-coinfected patients. On the basis of data in HIV-negative patients with cutaneous leishmaniasis and case reports in HIV-coinfected patients, first-line treatments include liposomal amphotericin B **(BIII)**, as outlined above, and pentavalent antimony (sodium stibogluconate, which is available in the United States through CDC, and meglumine antimoniate), 20 mg/kg body weight/day, by IV or IM route for 3–4 weeks depending on the form of the disease and the clinical response **(BIII)** *(1274, 1302)*. Pentavalent antimony was recently demonstrated to increase viral transcription and HIV replication in cultures of human peripheral blood mononuclear cells, raising concerns about its use in coinfected patients *(1312)*. A first-line parenteral treatment should be used for mucocutaneous and disseminated cutaneous disease and for localized cutaneous disease caused by *L. braziliensis*, the species most likely to cause mucocutaneous disease. Potential second-line alternatives for cutaneous leishmaniasis include miltefosine, topical paromomycin, intralesional pentavalent antimony, and local heat therapy; however, the effectiveness of these modalities is dependent on the infecting species of *Leishmania (1310, 1313, 1314)*.

Second-line treatment options for visceral leishmaniasis in HIV-coinfected patients include miltefosine and paromomycin. Miltefosine is an oral antileishmanial agent currently available in Germany, India, and several Latin American countries; cure rates of visceral leishmaniasis in HIV-negative patients are reported to be approximately 95% *(1315)*. The adult dose is 100 mg daily for 4 weeks. Although data to support its use among HIV-coinfected persons are limited, it is available for the treatment of visceral leishmaniasis in Europe under a compassionate use protocol **(CIII)** *(1316)*. Gastrointestinal side effects are the most common adverse effects but rarely limit treatment. Data from an Ethiopian population with a high prevalence of HIV-coinfection suggest that use of miltefosine was associated with a somewhat lower visceral leishmaniasis cure rate, but substantially lower mortality than pentavalent antimony *(1317)*. Miltefosine is teratogenic in experimental models, and its use in women of reproductive age requires a negative pregnancy test and effective contraception during and for at least 2 months after therapy. Paromomycin, a parenteral aminoglycoside, has been shown to be effective and safe in HIV-negative visceral leishmaniasis patients in India and is now in use in several countries **(BI)** *(1310)*.

Pentamidine isethionate has been used as a second-line alternative but is no longer recommended, because of toxicity that sometimes includes irreversible insulin-dependent diabetes mellitus **(DIII)**.

ART should be initiated or optimized following standard practice for HIV-infected patients **(AII)**. Appropriate use of ART has substantially improved the survival of coinfected patients in Europe and decreases the likelihood of relapse after antileishmanial therapy *(1277, 1289, 1318)*. Immunotherapy, including interferon-gamma and recombinant human granulocyte macrophage colony stimulating factor, has been used experimentally as an adjunct to antileishmanial treatment for refractory cases *(1319, 1320)*. However, a clinical trial of pentavalent antimony plus interferon-gamma for visceral leishmaniasis in HIV-coinfected patients was suspended when an interim analysis indicated that there was no advantage over pentavalent antimony alone *(1305)*. In addition, the use of interferon-gamma was reported to be associated with acceleration of KS in two patients with visceral leishmaniasis and HIV coinfection *(1292)*.

Monitoring and Adverse Events, Including Immune Reconstitution Inflammatory Syndrome (IRIS)

Patients receiving pentavalent antimonials should be monitored closely for adverse reactions, which are frequent and vary from mild phlebitis to death *(1302)*. Overall, at a dose of 20 mg/kg body weight/day, >60% of patients have one or more of the following reactions: thrombophlebitis, anorexia, myalgia, arthralgia, abdominal pain, elevation of liver transaminases, amylase or lipase, and in some patients, clinical pancreatitis. Occasional electrocardiographic changes might be observed (e.g., prolonged QT intervals and T-wave inversion). Rarely,

arrhythmias and sudden death have occurred *(1304, 1305)*. Severe adverse reactions to pentavalent antimony, including acute pancreatitis and leukopenia, appear to be more frequent in coinfected patients than in those without HIV *(1321)*.

Patients treated with amphotericin B should be monitored for dose-dependent nephrotoxicity, electrolyte disturbances, and infusion-related adverse reactions, which might be ameliorated by pretreatment with acetaminophen, diphenhydramine, or limited doses of corticosteroids **(CIII)**. Previous fluid expansion with colloidal fluids can help reduce the risk of nephrotoxicity during treatment **(CIII)**. The frequency of nephrotoxicity is lower for liposomal or lipid-associated preparations than for conventional amphotericin B *(1308)*. Conventional amphotericin B treatment might be associated with an increased risk of anemia *(1304)*.

Cases of newly symptomatic visceral and cutaneous leishmaniasis have been reported in association with the immune reconstitution syndrome following initiation of ART *(1322, 1323)*. However, existing experience regarding IRIS-associated leishmaniasis is insufficient to provide data for specific IRIS management guidelines. Leishmaniasis that manifests after initiation of ART requires specific therapy consistent with guidelines for initial treatment or management of relapse.

Management of Treatment Failure

For patients who fail to respond to initial therapy or experience a relapse after initial treatment, a repeat course of the initial regimen, or one of the recommended alternatives for initial therapy as outlined above, should be used **(AIII)**. The response rate for retreatment appears to be similar to that for initial therapy, although certain patients might evolve to a chronic disease state with serial relapses despite aggressive acute and maintenance therapies.

Preventing Recurrence

Clinical cure is dependent on concurrent T-cell-mediated parasite killing *(1324)*. Relapses, particularly of visceral leishmaniasis and disseminated cutaneous leishmaniasis, commonly follow cessation of therapy among immunosuppressed patients with AIDS. Among patients with visceral leishmaniasis who are not receiving or responding to ART, the risk of relapse at 6 and 12 months, in the absence of secondary prophylaxis (chronic maintenance therapy), is 60% and 90%, respectively *(1287, 1325)*. Therefore, secondary prophylaxis with an effective antileishmanial drug, administered at least every 2–4 weeks, is recommended, particularly for patients with visceral leishmaniasis and CD4+ counts <200 cells/μL **(AII)** *(1287, 1289, 1325, 1326)*. However, existing data are insufficient to recommend a specific regimen. The only published, randomized trial, which evaluated several patients, compared ABLC (3 mg/kg every 21 days) with no prophylaxis; this trial reported relapse rates of 50% versus 78%, respectively, after 1 year of follow-up *(1326)*. In retrospective studies, monthly pentavalent antimony or lipid formulations of amphotericin every 2–4 weeks was also associated with decreased relapse rates *(1289, 1325)*. Daily allopurinol, in a dose of 300 mg three times daily, used for maintenance therapy is less effective than monthly pentavalent antimony and is not recommended **(DIII)** *(1325)*. Although no published data on efficacy are available, maintenance therapy might be offered in immunocompromised patients with cutaneous leishmaniasis with multiple relapses after adequate treatment.

Discontinuing Secondary Prophylaxis (Chronic Maintenance Therapy)

For some investigators, clinical experience to date suggests that discontinuation of secondary antileishmanial prophylaxis can be considered in patients whose $CD4^+$ count rises above 200–350 cells/μL in response to ART, but that prophylaxis should be continued in those with counts below 200 cells/μL *(1327)*. Others, however, observe that ART might not be sufficient to control the disease, despite increases in $CD4^+$ counts and undetectable viral loads, suggesting that secondary prophylaxis should be maintained indefinitely *(1328, 1329)*. Although data are insufficient to provide a recommendation, discontinuation of secondary prophylaxis after successful treatment of leishmaniasis might be considered after a sustained (i.e., >3–6 months) increase in the $CD4^+$ count to levels >350 cells/μL after initiation of ART **(CIII)** *(1327)*.

Special Considerations During Pregnancy

Diagnostic considerations are the same among pregnant women as in nonpregnant women. Labeling for pentavalent antimony compounds (sodium stibogluconate, available in the United States through CDC, and meglumine antimoniate) states that these drugs are contraindicated for use among pregnant women, although various antimonial compounds were not teratogenic among chickens, rats, or sheep *(1330-1332)*. Good clinical and pregnancy outcomes have been reported for three pregnant women treated with meglumine antimoniate *(1333, 1334)* and five women treated with liposomal amphotericin B *(1335)*. Because of concerns about toxicity and lack of experience with use of pentavalent antimony compounds in human pregnancy, liposomal amphotericin B is the first choice for therapy of visceral leishmaniasis in pregnancy **(AIII)** *(1335)*. Pentavalent antimony should be the second choice **(AIII)**. Miltefosine is teratogenic and is contraindicated in pregnancy *(1310)*. Perinatal transmission of *Leishmania* spp. occurs rarely; eight documented cases have been reported.

No data on the risk of transmission of *Leishmania spp*. among HIV-infected pregnant women are available.

Chagas Disease

Epidemiology

American trypanosomiasis, or Chagas disease, is caused by *Trypanosoma cruzi,* a flagellated protozoan transmitted to mammals by haematophagous reduviid insects *(1337)*.

Chagas disease vectors have been reported in the Americas from 42ºN to 46ºS. The disease is distributed from the southern United States to the southern regions of Argentina and Chile. During a blood meal, *T. cruzi* parasites are deposited with the insect's feces when it defecates shortly after feeding. Humans usually become infected through mucous membranes or breaks in skin. Humans might also acquire trypanosomiasis from blood transfusions, and occasionally transplanted organ, maternal-fetal transmission, from ingesting contaminated food or drink, or from laboratory mishaps *(1338-1340)*.

Chagas disease affects approximately 10 million persons in the Americas *(1341)*. An estimated 50,000–100,000 persons in the United States have acquired *T. cruzi*; a majority are immigrants from disease-endemic areas. In the United States, vectorborne transmission of *T. cruzi* is rare, and the risk of transfusion-associated disease has been reduced recently. Screening of blood donations for anti-*T. cruzi* antibodies was introduced in 2007 by the American Red Cross and Blood Systems Laboratories *(1342)*.

In humans, acute *T. cruzi* infection is accompanied by moderate to high levels of parasitemia. After a few months, if untreated, the acute stage is followed by a lifelong chronic infection, characterized by low-grade and intermittent parasitemia in which tissue parasites are scarce and difficult to demonstrate. All patients with chronic infection are potentially able to transmit Chagas disease through triatomid insect bites, pregnancy, blood transfusion, or organ donation.

Among patients with HIV infection, symptomatic reactivation of chronic, latent *T. cruzi* infection can be triggered by profound immunosuppression *(1343-1346)*.

Clinical Manifestations

Chagas disease can be divided into two stages: acute and chronic. The acute stage of Chagas disease, usually observed among children, begins shortly after infection and lasts 1–2 months. This stage of the disease is often asymptomatic, although fever, malaise, anorexia, induration around the inoculation site (chagoma), or periocular edema (Romaña's sign) might be observed. Generalized lymphadenopathy, splenomegaly, cardiac failure, or meningoencephalitis can also occur during acute disease.

The relatively high parasitemia and symptoms (if present) in acute Chagas disease subside, and the patient enters an asymptomatic phase of the illness with low and intermittent parasitemia. After one or two decades, 10%–30% of infected patients experience chronic cardiac and/or digestive tract disease.

Persons with chronic Chagas disease who are HIV infected usually have higher levels of *T. cruzi* parasitemias than their counterparts who are HIV negative *(1345, 1347)*. Clinical reactivation occurs in HIV-infected patients, as it does with patients who are immunosuppressed by other processes *(1343-1346)*. One prospective study found reactivation in 11 (21%) of 53 patients during a median follow-up interval of 58 months *(1345)*. The majority of cases occur in patients with $CD4^+$ counts <200 cells/μL or prior OIs.

The clinical features of reactivated Chagas disease among patients with HIV infection differ from those observed in persons who are immunosuppressed from other causes. Approximately 75% of HIV-infected patients with reactivation experience an acute meningoencephalitis that is indistinguishable clinically from toxoplasmosis *(1343-1346)*. About 25%–50% of patients also have myocarditis at autopsy**,** but it is not usually the primary manifestation of reactivation.

Diagnosis

T. cruzi infection should be considered in the differential diagnosis of CNS mass lesions and cardiac disease (arrhythmias or heart failure) among patients with HIV infection who have epidemiologic risk factors for Chagas disease. The imaging pattern of brain chagoma is similar to that of cerebral toxoplasmosis, although chagomas tend to be larger than *Toxoplasma* lesions. CT and MRI show subcortical hypodense lesions that enhance with contrast or gadolinium. These lesions most often involve brain white matter. Histopathology shows inflammation and the presence of *T. cruzi* amastigotes in glial cells and, less often, in neurons. CSF shows a mild pleocytosis (lymphocyte predominance), increased protein, and *T. cruzi* trypomastigotes *(1343-1346)*.

A definitive diagnosis is established by brain biopsy or identification of the parasite (or its products) in tissue or blood. Direct tests for identifying *T. cruzi* microscopically are useful during the acute stage and in reactivation of chronic infection (e.g., in the setting of HIV infection). Circulating parasites are rarely detected microscopically in chronic Chagas disease in immunocompetent patients or in HIV-infected patients in the absence of reactivation. If observed in an immunocompromised HIV-positive patient, circulating parasites suggest reactivation and the need for treatment. Blood concentration techniques, such as capillary centrifugation (microhematocrit test), can improve sensitivity *(1348)*. In centrifuged blood,

T. cruzi trypomastigotes are found just above the buffy coat. Centrifugation of CSF also can be employed among patients with suspected CNS Chagas disease. Parasites also might be observed in lymph nodes, bone marrow, skin, pericardial fluid, and CNS mass lesions. Hemoculture is somewhat more sensitive than direct methods, but it might take 2–8 weeks to become positive. PCR of peripheral blood is not helpful for diagnosis of reactivation, because PCR is often positive in the absence of reactivation; however, PCR of CSF has been used to monitor reactivation in the CNS.

Serologic tests to detect the antibody responses to *T. cruzi* infection are useful for diagnosis of disease in chronically infected patients, to screen blood donors, and for seroepidemiologic studies. The techniques used include indirect hemagglutination, direct agglutination, complement fixation, indirect immunofluorescence, ELISA, and radioimmunoprecipitation assays. In the United States, multiple serologic tests are licensed for diagnosis. In late 2006, an ELISA assay for screening blood donors was licensed *(1342)*. As of December 2008, approximately 700 confirmed-positive donations have been reported *(1349)*. Detection of IgM antibodies is not sensitive, even during the acute stage of infection. Diagnosis based on serologic tests requires two positive tests performed with different techniques *(1350)*.

Although the serologic tests for *T. cruzi* infection are reasonably sensitive and specific, both false-positive and false-negative reactions have been reported. Therefore, the diagnosis of Chagas disease should not be excluded based on negative serologic tests if the patient has epidemiologic risk factors and clinical findings compatible with Chagas disease. In this instance, parasitologic testing directly (e.g., microscopic examination of brain tissue and/or demonstration of parasitemia) or with PCR are the best diagnostic strategies. Neonates born to mothers with chronic *T. cruzi* infection will have positive antibody tests, yet might not be infected; parasitologic tests and repeat antibody testing at 6 and 12 months are recommended in this instance *(1351)*.

Preventing Exposure

The reduviid insect vector of Chagas disease typically infests cracks and roofing of poor quality buildings constructed of adobe brick, mud, or thatch. The insects feed at night, and therefore HIV-infected persons living or visiting in areas where Chagas is endemic should avoid overnight stays in such dwellings or sleeping outdoors. They also should be aware that blood products in the United States or abroad might not always be screened routinely for *T. cruzi.* Transfusion, organ transplantation, and MTCT are the more likely infection routes in the United States. Better housing conditions and less efficient vectors might explain the lower risk of vectorial transmission in this country *(1352)*.

No drugs or vaccines for preventing *T. cruzi* infection are available. Preventive measures include spraying infested dwellings with residual-action insecticide and if sleeping outdoors or in suspect dwellings cannot be avoided then sleeping under insecticide-treated bednets,

Preventing Disease

The clinical manifestations of Chagas disease in HIV-positive persons usually represent reactivation and not acute infection with *T. cruzi*. All HIV-infected persons with epidemiologic risk factors for Chagas disease should be tested for antibody to *T. cruzi* to detect latent infection *(1353)*. Antibody-positive patients who have not been previously treated, who are likely to have been infected for less than two decades, and who are without signs or symptoms of Chagas disease might benefit from a single course of medication with benznidazole or nifurtimox **(CIII)**. Limited data and a lack of consensus exist regarding the benefit of chemotherapy in patients with longer-standing infection or chronic disease manifestations.

Optimization of ART might help prevent Chagas reactivation. The majority of cases have occurred in patients who were not taking ART.

Treatment of Disease

Chemotherapy of Chagas disease with benznidazole or nifurtimox is effective in reducing parasitemia and preventing clinical manifestations for patients with acute, early chronic, and reactivated disease. However, these drugs are limited in achieving parasitological cure. Consultation with a specialist should be sought. Benznidazole, 5–8 mg/kg body weight/day for 30–60 days, is the initial treatment most commonly recommended **(BIII)**. Nifurtimox, 8–10 mg/kg body weight/day, administered for 90–120 days is an alternative **(CIII).** However, the duration of therapy with either of these agents has not been studied for persons coinfected with HIV. Mortality is high, even in patients who receive chemotherapy. Limited data suggest that early recognition and treatment of reactivation might improve prognosis *(1345).* Neither anti-trypanosomal drug is licensed in the United States; however, the drugs are available from the CDC Drug Service (404-639-3670) for use under investigational protocols.

ART is likely to reduce or prevent initial reactivation of *T. cruzi* or its recurrence. ART should be initiated or optimized once a patient with acute disease is clinically stable **(AIII).**

Monitoring and Adverse Events, Including Immune Reconstitution Inflammatory Syndrome (IRIS)

Patients undergoing treatment should be monitored closely because both benznidazole and nifurtimox are toxic *(1354)*. Benznidazole causes peripheral neuropathy, rash, and granulocytopenia. Nifurtimox causes anorexia, nausea, vomiting, abdominal pain and weight loss, restlessness, tremors, and peripheral neuropathy. The adverse effects of both drugs wane when the drugs are discontinued.

No reports are available regarding *T. cruzi* infection and IRIS.

Management of Treatment Failure

Although no data are available, retreatment with benznidazole or nifurtimox is recommended for HIV-infected patients who fail to respond or who relapse following initial therapy **(AIII)**.

Preventing Recurrence

Patients with HIV infection are potentially at risk for recurrent or relapsing clinical manifestations because of intermittent reactivation of chronic infection. The drugs are only partially effective in the chronic stage of disease, are suppressive rather than curative, and might require lifelong administration to prevent relapse in the setting of continued immunosuppression. Because the drugs are toxic and experience with their use in HIV-infected patients is limited, expert advice about indicators and regimens should be sought. Whether secondary prophylaxis or chronic maintenance therapy should be used in HIV-infected patients with latent Chagas disease is unclear, particularly when modern ART is used.

Special Considerations During Pregnancy

The seroprevalence of *T. cruzi* infection among pregnant women in areas where the disease is endemic in Latin America can be as high as 50% in urban areas and 81% in rural areas. In the United States, one study of 3,765 pregnant women in Houston, Texas, confirmed antibody to *T. cruzi* in 0.4% of Hispanic women and 0.1% of non-Hispanic women *(1355)*.

Perinatal transmission rates among general populations of pregnant women seropositive for antibodies to *T. cruzi* range from 2% to 10% *(1356)*. The effect of concurrent HIV infection in the mother on risk of perinatal transmission of *T. cruzi* is not known; however, limited data available at present suggest that rates of perinatal transmission might be higher for HIV-infected women than the rates previously documented for immunocompetent mothers *(1345)*. Infants coinfected with HIV and *T. cruzi* might be more likely to have symptoms, especially neurologic symptoms *(1351, 1357)*.

Congenital infection with *T. cruzi* might increase the risk of spontaneous abortion, stillbirth, and low birthweight *(1356)*. Congenital Chagas disease in newborn infants ranges from subclinical to life threatening with severe neurologic and cardiac disease.

Minimal data are available on potential reproductive toxicity of benznidazole and nifurtimox, although both drugs have been associated with increased detection of chromosomal aberrations in children being treated for Chagas disease *(1358, 1359)*. Benznidazole crosses the placenta in rats and covalently binds to fetal proteins *(1360)*. Because of the toxicity and limited experience with use of these drugs in pregnancy, treatment of acute *T. cruzi* infection among pregnant women should only be undertaken in consultation with a specialist in this area, and treatment of chronic disease should be considered only after completion of the pregnancy. For HIV-infected pregnant women with symptomatic reactivation of *T. cruzi* infection, the immune response should be maximized with ART **(AIII).**

Isosporiasis

Epidemiology

Isosporiasis occurs worldwide but predominantly in tropical and subtropical regions. Immunocompromised persons, including those with AIDS, are at increased risk for chronic, debilitating illness *(30, 1361-1366)*. Although *Isospora belli* completes its life cycle in humans, the oocysts shed in the feces of infected persons must mature (sporulate) outside the host, in the environment, to become infective. On the basis of limited data, the maturation process is completed in approximately 1–2 days but might occur in <24 hours *(1361)*. Infection results from ingestion of sporulated oocysts (e.g., in contaminated food or water). After ingestion, the parasite invades enterocytes in the small intestine. Ultimately, immature oocysts are produced and shed in stool.

Clinical Manifestations

The most common manifestation is watery, nonbloody diarrhea, which may be associated with abdominal pain, cramping, anorexia, nausea, vomiting, and low-grade fever. The diarrhea can be profuse and prolonged, particularly in immunocompromised patients, resulting in severe dehydration, weight loss, and malabsorption *(1365-1370)*. Acalculous cholecystitis *(1361, 1371)* and reactive arthritis *(1372)* have also been reported.

Diagnosis

Typically, infection is diagnosed by detecting *Isospora* oocysts (dimensions, 23–36 μm by 12–17 μm) in fecal specimens *(1361)*. Oocysts might be shed intermittently and at low levels, even by persons with profuse diarrhea. Diagnosis might be facilitated by repeated stool examinations with sensitive methods (e.g., oocysts stain bright red with modified acid-

fast techniques and they autofluoresce when viewed by UV fluorescence microscopy) *(1361, 1373)*. Infection also can be diagnosed by detecting oocysts in duodenal aspirates/mucus or developmental stages of the parasite in intestinal biopsy specimens *(1361, 1369)*. Extraintestinal infection (e.g., in the biliary tract, lymph nodes, spleen, and liver) has been documented in postmortem examinations of patients with AIDS *(1361, 1374-1376)*.

Preventing Exposure

Not applicable to residents of the United States.

Preventing Disease

In some settings, chemoprophylaxis with TMP-SMX has been associated with a lower incidence or prevalence of isosporiasis *(30, 1362, 1363)*. In a randomized, placebo-controlled trial, daily TMP-SMX (160/800 mg) was protective against isosporiasis in persons with early-stage HIV infection (WHO clinical stage 2 or 3 at enrollment) *(30)*. In an observational study, the incidence of isosporiasis decreased after widespread introduction of ART, except among persons with $CD4^+$ counts <50 cells/μL *(1362)*. After adjustment for the $CD4^+$ count, the risk of isosporiasis was substantially lower among persons receiving prophylaxis with TMP-SMX, sulfadiazine, or pyrimethamine (unspecified regimens). In analyses of data from a county AIDS surveillance registry during the pre-ART era, the prevalence of isosporiasis was lower in persons with (vs. without) a history of PCP—indirect evidence of a protective effect from use of TMP-SMX for PCP *(1363)*. However, insufficient evidence is available to support a general recommendation for primary prophylaxis for isosporiasis per se **(DIII)**.

Treatment of Disease

Clinical management includes fluid and electrolyte support for dehydrated patients and nutritional supplementation for malnourished patients **(AIII)**. TMP-SMX is the antimicrobial agent of choice for treatment of isosporiasis **(AI).** It is the only agent whose use is supported by substantial published data and clinical experience. Therefore, potential alternative therapies should be reserved for patients with documented sulfa intolerance or treatment failure **(AIII).**

Three studies among HIV-infected patients in Haiti have demonstrated the effectiveness of various treatment regimens of TMP-SMX and the need for and effectiveness of secondary prophylaxis *(1365, 1366, 1377)*. The patients were not receiving ART, and laboratory indicators of immunodeficiency (e.g., $CD4^+$ counts) were not specified. On the basis of the initial studies *(1365, 1366)*, the traditional treatment regimen has been a 10-day course of TMP-SMX (160/800 mg) administered four times a day **(AII)** *(505)*. In a more recent study, TMP-SMX (160/800 mg) administered twice a day was effective **(BI)** *(1377)*. Although experience using two versus four daily doses of TMP-SMX (160/800 mg) is limited, one approach would be to start with this regimen but to increase the daily dose and/or the duration of therapy (up to 3–4 weeks) *(1365, 1369)* if symptoms worsen or persist **(BIII).** Intravenous administration of TMP-SMX should be considered for patients with potential or documented malabsorption.

Limited data suggest that therapy with pyrimethamine–sulfadiazine and pyrimethamine–sulfadoxine might be effective *(1361, 1368, 1369, 1378-1380)*. However, the combination of pyrimethamine plus sulfadoxine is not typically recommended for use in the United States **(CIII)**; it has been associated with an increased risk of severe cutaneous reactions, including Stevens-Johnson syndrome *(125)*, and pyrimethamine and sulfadoxine are slowly cleared from the body after therapy is discontinued.

Single-agent therapy with pyrimethamine has been used with anecdotal success for treatment and prevention of isosporiasis *(1362, 1381, 1382)*. Pyrimethamine (50–75 mg/day) — plus leucovorin (10–25 mg/day) to prevent myelosuppression — might be an effective treatment alternative (e.g., it is the traditional option for sulfa-intolerant patients) **(BIII).**

Monitoring and Adverse Events, Including Immune Reconstitution Inflammatory Syndrome (IRIS)

Patients should be monitored for clinical response and adverse events. Among patients with AIDS, TMP-SMX therapy is commonly associated with side effects (e.g., rash, fever, leukopenia, thrombocytopenia, elevated transaminase levels). IRIS has not been reported in association with treatment of isosporiasis.

Management of Treatment Failure

If symptoms worsen or persist despite approximately 5–7 days of TMP-SMX therapy, the possibilities of noncompliance, malabsorption, and concurrent infections/enteropathies should be considered; the TMP-SMX regimen (i.e., daily dose, duration, and mode of administration) also should be reevaluated. For patients with documented sulfa intolerance or treatment failure, use of a potential alternative agent (e.g., pyrimethamine) should be considered. Ciprofloxacin might be considered as a second-line agent **(CI).** On the basis of limited data from a randomized, controlled trial in Haiti, ciprofloxacin (500 mg twice daily for 7 days) is less effective than TMP-SMX but might have modest activity against *I. belli (1377)*.

Unsubstantiated or mixed data are available for albendazole *(1382-1384)*, nitazoxanide *(1385, 1386)*, doxycycline *(1387)*, the macrolides roxithromycin and spiramycin *(1379, 1388, 1389)*, and the veterinary anticoccidial agent diclazuril

(1390, 1391) **(CIII)**. Limited data suggest that drugs such as metronidazole, quinacrine, iodoquinol, paromomycin, and furazolidone are ineffective **(DIII)** *(1367, 1379-1381, 1388, 1390)*. Apparent or partial responses, if noted, might be attributable to treatment of concomitant infections or to nonspecific effects.

Preventing Recurrence

Patients with $CD4^+$ counts <200 cells/μL should receive secondary prophylaxis (chronic maintenance therapy) with TMP-SMX **(AI).** In studies in Haiti, approximately 50% of patients who did not receive secondary prophylaxis had symptomatic recurrences approximately 2 months after completing a course of TMP-SMX therapy, relapses rapidly responded to retreatment, and secondary prophylaxis decreased the risk for relapse *(1365, 1366, 1377)*. In a randomized, placebo-controlled trial, no symptomatic recurrences were noted among patients who received maintenance therapy with thrice-weekly TMP-SMX (160/800 mg) **(AI)** *(1366)*. Daily TMP-SMX (160/800 mg) and thrice-weekly TMP-SMX (320/1,600 mg) have been effective **(BIII)** *(1364, 1369)*.

In sulfa-intolerant patients, pyrimethamine (25 mg/day) with leucovorin (5–10 mg/day) has been used **(BIII)** *(1381)*. Ciprofloxacin (500 mg thrice weekly) might be considered as a second-line alternative **(CI)** *(1377)*.

Discontinuing Secondary Prophylaxis

The concern of discontinuing prophylaxis has not been evaluated in a clinical trial. Chemoprophylaxis probably can be safely discontinued in patients without evidence of active *I. belli* infection who have a sustained increase in the $CD4^+$ count to levels >200 cells/μL for >6 months after initiation of ART **(BIII)**.

Special Considerations During Pregnancy

TMP-SMX is usually the agent of choice for primary treatment and secondary prophylaxis in pregnant women, as it is for nonpregnant women. Although first-trimester exposure to trimethoprim might be associated with a small increased risk of birth defects *(173-176)*, in the setting of maternal symptomatic *I. belli* infection, therapy with TMP-SMX should be provided. Because of concerns about possible teratogenicity associated with drug exposure during the first trimester, clinicians might withhold secondary prophylaxis during the first trimester and treat only symptomatic infection. Although pyrimethamine has been associated with birth defects in animals, limited human data have not suggested an increased risk of defects *(228)*. Human data about the use of ciprofloxacin during several hundred pregnancies have not suggested an increased risk of birth defects or cartilage abnormalities *(395)*.

TABLE 1. Prophylaxis to prevent first episode of opportunistic disease

Pathogen	Indication	First choice	Alternative
Pneumocystis pneumonia (PCP)	CD4+ count <200 cells/μL **(AI)** or oropharyngeal candidiasis **(AII)** CD4+ <14% or history of AIDS-defining illness **(BII)** CD4+ count >200 but <250 cells/μL if monitoring CD4+ count every 1–3 months is not possible **(BII)**	Trimethoprim-sulfamethoxazole (TMP-SMX), 1 DS PO daily **(AI)**; or 1 SS daily **(AI)**	• TMP-SMX 1 DS PO tiw **(BI)**; or • Dapsone 100 mg PO daily or 50 mg PO bid **(BI)**; or • Dapsone 50 mg PO daily + pyrimethamine 50 mg PO weekly + leucovorin 25 mg PO weekly **(BI)**; or • Aerosolized pentamidine 300 mg via Respigard II™ nebulizer every month **(BI)**; or • Atovaquone 1,500 mg PO daily **(BI)**; or • Atovaquone 1,500 mg + pyrimethamine 25 mg + leucovorin 10 mg PO daily **(CIII)**
Toxoplasma gondii encephalitis	Toxoplasma IgG positive patients with CD4+ count <100 cells/μL **(AII)** Seronegative patients receiving PCP prophylaxis not active against toxoplasmosis should have toxoplasma serology retested if CD4+ count decline to <100 cells/μL **(CIII)** Prophylaxis should be initiated if seroconversion occurred **(AII)**	TMP-SMX, 1 DS PO daily **(AII)**	• TMP-SMX 1 DS PO tiw **(BIII)**; or • TMP-SMX 1 SS PO daily **(BIII)**; • Dapsone 50 mg PO daily + pyrimethamine 50 mg PO weekly + leucovorin 25 mg PO weekly **(BI)**; or • (Dapsone 200 mg + pyrimethamine 75 mg + leucovorin 25 mg) PO weekly **(BI)**; • (Atovaquone 1,500 mg +/- pyrimethamine 25 mg + leucovorin 10 mg) PO daily **(CIII)**
Mycobacterium tuberculosis infection (TB) (Treatment of latent TB infection or LTBI)	(+) diagnostic test for LTBI, no evidence of active TB, and no prior history of treatment for active or latent TB **(AI)**; (-) diagnostic test for LTBI, but close contact with a person with infectious pulmonary TB and no evidence of active TB **(AII)**; A history of untreated or inadequately treated healed TB (i.e., old fibrotic lesions) regardless of diagnostic tests for LTBI and no evidence of active TB **(AII)**	Isoniazid (INH) 300 mg PO daily **(AII)** or 900 mg PO biw **(BII)** for 9 months – both plus pyridoxine 50 mg PO daily **(BIII)**; or For persons exposed to drug-resistant TB, selection of drugs after consultation with public health authorities **(AII)**	• Rifampin (RIF) 600 mg PO daily x 4 months **(BIII)**; or • Rifabutin (RFB) (dose adjusted based on concomitant ART) x 4 months **(BIII)**
Disseminated *Mycobacterium avium* complex (MAC) disease	CD4+ count <50 cells/μL – after ruling out active MAC infection **(AI)**	Azithromycin 1,200 mg PO once weekly **(AI)**; or Clarithromycin 500 mg PO bid **(AI)**; or Azithromycin 600 mg PO twice weekly **(BIII)**	• RFB 300 mg PO daily **(BI)** (dosage adjustment based on drug-drug interactions with ART); rule out active TB before starting RFB
Streptococcus pneumoniae infection	CD4+ count >200 cells/μL and no receipt of pneumococcal vaccine in the past 5 years **(AII)** CD4+ count <200 cells/μL – vaccination can be offered **(CIII)** In patients who received polysaccharide pneumococcal vaccination (PPV) when CD4+ count <200 cells/μL, but has increased to >200 cells/μL in response to ART **(CIII)**	23-valent PPV 0.5 mL IM x 1 **(BII)** Revaccination every 5 years may be considered **(CIII)**	
Influenza A and B virus infection	All HIV-infected patients **(AIII)**	Inactivated influenza vaccine 0.5 mL IM annually **(AIII)**	
Histoplasma capsulatum infection	CD4+ count ≤150 cells/μL and at high risk because of occupational exposure or live in a community with a hyperendemic rate of histoplasmosis (>10 cases/100 patient-years) **(CI)**	Itraconazole 200 mg PO daily (CI)	
Coccidioidomycosis	Positive IgM or IgG serologic test in a patient from a disease-endemic area; and CD4+ count <250 cells/μL **(CIII)**	Fluconazole 400 mg PO daily **(CIII)** Itraconazole 200 mg PO bid **(CIII)**	

TABLE 1. (*Continued*) Prophylaxis to prevent first episode of opportunistic disease

Pathogen	Indication	First choice	Alternative
Varicella-zoster virus (VZV) infection	Pre-exposure prevention: Patients with CD4+ count ≥200 cells/μL who have not been vaccinated, have no history of varicella or herpes zoster, or who are seronegative for VZV **(CIII)** Note: routine VZV serologic testing in HIV-infected adults is not recommended Post-exposure – close contact with a person who has active varicella or herpes zoster: For susceptible patients (those who have no history of vaccination or of either condition, or are known to be VZV seronegative) **(AIII)**	Pre-exposure prevention: Primary varicella vaccination (Varivax™), 2 doses (0.5 mL SQ) administered 3 months apart **(CIII)** If vaccination results in disease because of vaccine virus, treatment with acyclovir is recommended **(AIII)** Post-exposure therapy: Varicella-zoster immune globulin (VariZIG™) 125 IU per 10 kg (maximum of 625 IU) IM, administered within 96 hours after exposure to a person with active varicella or herpes zoster **(AIII)** Note: As of June 2007, VariZIG can be obtained only under a treatment IND (1-800-843-7477, FFF Enterprises)	• VZV-susceptible household contacts of susceptible HIV-infected persons should be vaccinated to prevent potential transmission of VZV to their HIV-infected contacts **(BIII)** Alternative post-exposure therapy: • Post exposure varicella vaccine (Varivax) 0.5 mL SQ x 2 doses, 3 months apart if CD4+ count >200 cells/μL **(CIII)**; or • Pre-emptive acyclovir 800 mg PO 5x/day for 5 days **(CIII)** • These two alternatives have not been studied in the HIV population
Human Papillomavirus (HPV) infection	Women aged 15–26 yrs **(CIII)**	HPV quadravalent vaccine 0.5 mL IM months 0, 2, and 6 **(CIII)**	
Hepatitis A virus (HAV) infection	HAV-susceptible patients with chronic liver disease, or who are injection-drug users, or men who have sex with men **(AII).** Certain specialists might delay vaccination until CD4+ count >200 cells/μL **(CIII)**	Hepatitis A vaccine 1 mL IM x 2 doses - at 0 & 6–12 months **(AII)** IgG antibody response should be assessed 1 month after vaccination; non-responders should be revaccinated **(BIII)**	
Hepatitis B virus (HBV) infection	All HIV patients without evidence of prior exposure to HBV should be vaccinated with HBV vaccine, including patients with CD4+ count <200 cells/μL **(AII)** *Patients with isolated anti-HBc:* **(BII)** (consider screening for HBV DNA before vaccination to rule out occult chronic HBV infection) *Vaccine non-responders:* Defined as anti-HBs <10 IU/mL 1 month after a vaccination series For patients with low CD4+ count at the time of first vaccination series, certain specialists might delay revaccination until after a sustained increase in CD4+ count with ART.	Hepatitis B vaccine IM (Engerix-B® 20 μg/mL or Recombivax HB® 10 μg/mL) at 0, 1, and 6 months **(AII)** Anti-HBs should be obtained one month after completion of the vaccine series **(BIII)** Revaccinate with a second vaccine series **(BIII)**	Some experts recommend vaccinating with 40 μg doses of either vaccine **(CIII)** Some experts recommend revaccinating with 40 μg doses of either vaccine **(CIII)**
Malaria	Travel to disease-endemic area	Recommendations are the same for HIV-infected and -uninfected patients. One of the following three drugs is usually recommended depending on location: atovaquone/proguanil, doxycycline, or mefloquine. Refer to the following website for the most recent recommendations based on region and drug susceptibility. http://www.cdc.gov/malaria/ **(AIII)**	

Definitions of abbreviations: DS = double strength; PO = by mouth; SS = single strength; bid = twice daily; tiw = 3 times weekly; SQ = subcutaneous; IM = intramuscular

TABLE 2. Drug therapy for treatment and chronic maintenance therapy of AIDS-associated opportunistic infections in adults and adolescents

Opportunistic infection	Preferred therapy, duration of therapy, chronic maintenance	Alternative therapy	Other options/issues
Pneumocystis pneumonia (PCP)	Preferred treatment for moderate to severe PCP ▪ Trimethoprim-sulfamethoxazole (TMP-SMX): [15–20 mg TMP and 75–100 mg SMX]/kg/day IV administered q6h or q8h **(AI)**, may switch to PO after clinical improvement **(AI)** ▪ Duration of therapy: 21 days **(AII)**	Alternative therapy for moderate to severe PCP ▪ Pentamidine 4 mg/kg IV daily infused over ≥60 minutes **(AI)**, certain specialists reduce dose to 3 mg/kg IV daily because of toxicities **(BI)**; or ▪ Primaquine 15–30 mg (base) PO daily plus clindamycin 600–900 mg IV q6h to q8h or clindamycin 300–450 mg PO q6h to q8h **(AI)**	Indications for corticosteroids **(AI)** PaO_2 <70 mmHg at room air or alveolar-arterial O_2 gradient >35 mmHg Prednisone doses (beginning as early as possible and within 72 hours of PCP therapy) **(AI)**: Days 1–5 40 mg PO bid Days 6–10 40 mg PO daily Days 11–21 20 mg PO daily IV methylprednisolone can be administered as 75% of prednisone dose Benefits of corticosteroid if started after 72 hours of treatment is unknown, but a majority of clinicians will use it in patients with moderate to severe PCP **(BIII)** Whenever possible, patients should be tested for G6PD deficiency before use of primaquine
	Preferred treatment for mild to moderate PCP ▪ Same daily dose of TMP-SMX as above, administered PO in 3 divided doses **(AI)**; or ▪ TMP-SMX (160 mg/800 mg or DS) 2 tablets tid **(AI)** ▪ Duration of therapy: 21 days **(AII)**	Alternative therapy for mild-to-moderate PCP ▪ Dapsone 100 mg PO daily and TMP 15 mg/kg/day PO (3 divided dose) **(BI)**; or ▪ Primaquine 15–30 mg (base) PO daily plus clindamycin 300–450 mg PO q6h to q8h **(BI)**; or ▪ Atovaquone 750 mg PO bid with food **(BI)**	
	Preferred secondary prophylaxis ▪ TMP-SMX (160 mg/800 mg or DS) tablet PO daily **(AI)**; or ▪ TMP-SMX (80 mg/400 mg or SS) tablet PO daily **(AI)**	Alternative secondary prophylaxis ▪ TMP-SMX (160 mg/800 mg or DS) PO tiw **(BI)** ▪ Dapsone 50 mg PO bid or 100 mg PO daily **(BI)**; or ▪ Dapsone 50 mg PO daily plus pyrimethamine 50 mg PO weekly plus leucovorin 25 mg PO weekly **(BI)**; or ▪ Dapsone 200 mg PO plus pyrimethamine 75 mg PO plus leucovorin 25 mg PO weekly **(BI)**; or ▪ Aerosolized pentamidine 300 mg every month via Respirgard II™ nebulizer **(BI)**; or ▪ Atovaquone 1,500 mg PO daily **(BI)**; or ▪ Atovaquone 1,500 mg + pyrimethamine 25 mg + leucovorin 10 mg PO daily **(CIII)**	

TABLE 2. (*Continued*) Drug therapy for treatment and chronic maintenance therapy of AIDS-associated opportunistic infections in adults and adolescents

Opportunistic infection	Preferred therapy, duration of therapy, chronic maintenance	Alternative therapy	Other options/issues
Toxoplasma gondii encephalitis (TE)	Preferred therapy ▪ Pyrimethamine 200 mg PO x 1, then 50 mg (<60 kg) to 75 mg (≥60 kg) PO daily plus sulfadiazine 1,000 mg (<60 kg) to 1,500 mg (≥60 kg) PO q6h plus leucovorin 10–25 mg PO daily (can increase 50 mg) **(AI)** Duration for acute therapy ▪ At least 6 weeks **(BII)**; longer duration if clinical or radiologic disease is extensive or response is incomplete at 6 weeks	Alternative therapy regimens • Pyrimethamine (leucovorin)* plus clindamycin 600 mg IV or PO q6h **(AI)**; or • TMP-SMX (5 mg/kg TMP and 25 mg/kg SMX) IV or PO bid **(BI)**; or • Atovaquone 1,500 mg PO bid with food (or nutritional supplement) plus pyrimethamine (leucovorin)* **(BII)**; or • Atovaquone 1,500 mg PO bid with food (or nutritional supplement) plus sulfadiazine 1,000–1,500 mg PO q6h **(BII)**; or • Atovaquone 1,500 mg PO bid with food **(BII)**; or • Pyrimethamine (leucovorin)* plus Azithromycin 900–1200 mg PO daily **(BII)**	Adjunctive corticosteroids (e.g., dexamethasone) should be administered when clinically indicated only for treatment of mass effect attributed to focal lesions or associated edema **(BIII)**; discontinue as soon as clinically feasible Anticonvulsants should be administered to patients with a history of seizures **(AIII)** and continued through the acute treatment; but should not be used prophylactically **(DIII)**
	Preferred chronic maintenance therapy ▪ Pyrimethamine 25–50 mg PO daily plus sulfadiazine 2,000–4,000 mg PO daily (in two to four divided doses) plus leucovorin 10–25 mg PO daily **(AI)**	Alternative chronic maintenance therapy/ secondary prophylaxis • Clindamycin 600 mg PO every 8 hours plus pyrimethamine 25–50 mg PO daily plus leucovorin 10–25 PO daily **(BI)** [should add additional agent to prevent PCP **(AII)**]; or • Atovaquone 750 mg PO every 6–12 hours +/- [(pyrimethamine 25 mg PO daily plus leucovorin 10 mg PO daily) or sulfadiazine 2,000–4,000 mg PO] daily **(BII)**	
Cryptosporidiosis	Preferred therapy ▪ Initiate or optimize ART for immune restoration **(AII)** ▪ Symptomatic treatment of diarrhea **(AIII)** ▪ Aggressive oral or IV rehydration & replacement of electrolyte loss **(AIII)**	Alternative therapy for cryptosporidiosis ▪ A trial of nitazoxanide 500–1,000 mg PO bid with food for 14 days **(CIII)** + optimized ART, symptomatic treatment and rehydration & electrolyte replacement	Use of antimotility agents such as loperamide or tincture of opium might palliate symptoms **(BIII)**

* Pyrimethamine and leucovorin doses – same as in "Preferred therapy" for toxoplasmosis.

TABLE 2. (*Continued*) Drug therapy for treatment and chronic maintenance therapy of AIDS-associated opportunistic infections in adults and adolescents

Opportunistic infection	Preferred therapy, duration of therapy, chronic maintenance	Alternative therapy	Other options/issues
Microsporidiosis	Initiate or optimize ART; immune restoration to CD4+ count >100 cells/μL is associated with resolution of symptoms of enteric microsporidiosis **(AII)**		Severe dehydration, malnutrition, and wasting should be managed by fluid support and nutritional supplement **(AIII)** Antimotility agents can be used for diarrhea control if required **(BIII)**
	Preferred therapy for gastrointestinal infections caused by *Enterocytozoon bienuesi* ▪ Fumagillin 20 mg PO tid (not available in U.S.) **(BII)** ▪ TNP-470 (a synthetic analog of fumagillin) might also be effective (not available in U.S.) **(BIII)**	Alternative therapy for gastrointestinal infections caused by *E. bienuesi* ▪ Nitazoxanide 1,000 mg bid with food for 60 days – effects might be minimal for patients with low CD4+ count **(CIII)**	
	Preferred therapy for disseminated (not ocular) and intestinal infection attributed to microsporidia other than *E. bienuesi* and *Vittaforma corneae* ▪ Albendazole 400 mg PO bid **(AII)**, continue until CD4+ count >200 cells/μL for >6 months after initiation of ART **(BIII)**	Alternative therapy for disseminated disease ▪ Itraconazole 400 mg PO daily plus albendazole 400 mg PO bid for disseminated disease attributed to *Trachipleistophora* or *Anncaliia* **(CIII)**	
	For ocular infection ▪ Topical fumagillin bicylohexylammonium (Fumidil B) 3 mg/mL in saline (fumagillin 70 μg/mL) eye drops - 2 drops every 2 hours for 4 days, then 2 drops qid (investigational use only in U.S.) **(BII)** plus albendazole 400 mg PO bid for management of systemic infection **(BIII)** ▪ Treatment should be continued indefinitely to prevent recurrence or relapse **(BIII)**		

TABLE 2. (*Continued*) Drug therapy for treatment and chronic maintenance therapy of AIDS-associated opportunistic infections in adults and adolescents

Opportunistic infection	Preferred therapy, duration of therapy, chronic maintenance	Alternative therapy	Other options/issues
Mycobacterium tuberculosis (TB)	Empiric treatment should be initiated and continued in HIV-infected persons in whom TB is suspected until all diagnostic work-up is complete **(AII)** **Treatment of drug-susceptible active TB disease** (*refer to Table 3 for dosing recommendations*) Initial phase (2 months) **(AI)** Isoniazid (INH)† + [rifampin (RIF) or rifabutin (RFB)] + pyrazinamide (PZA) + ethambutol (EMB); if drug susceptibility report shows sensitivity to INH & RIF and PZA, then EMB may be discontinued before 2 months of treatment is completed **(AI)** Continuation phase ▪ INH + (RIF or RFB) daily or tiw **(AIII)** or biw (if CD4+ count >100/μL) **(CIII)** Duration of therapy: *Pulmonary TB* – 6 months **(AI)** *Pulmonary TB w/ cavitary lung lesions & (+) culture after 2 months of TB treatment* **(AII)** – 9 months *Extrapulmonary TB w/ CNS, bone, or joint infections* – 9 to 12 months **(AII);** *Extrapulmonary TB in other sites* – 6 to 9 months **(AII)**	**Treatment for drug-resistant active TB** Resistant to INH ▪ Discontinue INH (and streptomycin, if used) ▪ (RIF or RFB) + EMB + PZA for 6 months **(BII)**; or ▪ (RIF or RFB) + EMB for 12 months (preferably with PZA during at least the first 2 months) **(BII)** ▪ A fluoroquinolone may strengthen the regimen for patients with extensive disease **(CIII)** Resistant to rifamycins ▪ INH + PZA + EMB + a fluoroquinolone for 2 months, followed by 10–16 additional months with INH + EMB + fluoroquinolone **(BIII)** ▪ Amikacin or capreomycin may be included in the first 2–3 months for patients with rifamycin resistance & severe disease **(CIII)** Multidrug resistant (MDR, i.e., INH & RIF resistant) or extensively drug resistant (XDR, i.e., resistance to INH & RIF, fluoroquinolone & at least 1 injectable agent) TB ▪ Therapy should be individualized based on resistance pattern and with close consultation with experienced specialist **(AIII)**	Directly observed therapy (DOT) is recommended for all HIV patients undergoing treatment for active TB **(AII)** Initial phase of TB treatment may also be administered 5 days weekly (40 doses) **(AII)**, or tiw (24 doses) **(BII)** by DOT For CNS disease, corticosteroid should be initiated as early as possible and continued for 6–8 weeks **(AII)** RIF is not recommended for patients receiving HIV protease inhibitors (PI) because of its induction of PI metabolism **(EII)** RFB is a less potent CYP 3A4 inducer than RIF and is preferred in patients receiving PIs Rifapentine administered once weekly can result in development of resistance in HIV-infected patients and is not recommended **(EI)** Therapeutic drug monitoring should be considered in patients receiving rifamycin and interacting ART Paradoxical reaction that is not severe may be treated with nonsteroidal anti-inflammatory drugs (NSAIDs) without a change in anti-TB or anti-HIV therapy (**BIII**) For severe paradoxical reaction, may consider prednisone or methylprednisolone 1 mg/kg of body weight, gradually reduced after 1–2 weeks **(BIII)**

† All patients receiving INH should receive pyridoxine 25–50 mg PO daily **(BIII).**

TABLE 2. (*Continued*) Drug therapy for treatment and chronic maintenance therapy of AIDS-associated opportunistic infections in adults and adolescents

Opportunistic infection	Preferred therapy, duration of therapy, chronic maintenance	Alternative therapy	Other options/issues
Disseminated *Mycobacterium avium* complex (MAC) disease	Preferred therapy for disseminated MAC At least 2 drugs as initial therapy with ▪ Clarithromycin 500 mg PO bid **(AI)** + ethambutol 15 mg/kg PO daily **(AI)** Addition of rifabutin may also be considered: ▪ Rifabutin 300 mg PO daily (dosage adjusted may be necessary based on drug-drug interactions) **(CI)**	Alternative therapy for disseminated MAC (e.g., when drug interactions or intolerance precludes the use of clarithromycin) ▪ Azithromycin 500–600 mg + ethambutol 15 mg/kg PO daily **(AII)** Addition of a third or fourth drug should be considered for patients with advanced immunosuppression (CD4+ count <50 cells/μL), high mycobacterial loads (>2 log CFU/mL of blood), or in the absence of effective ART **(CIII)** ▪ Amikacin 10–15 mg/kg IV daily; or ▪ Streptomycin 1 gm IV or IM daily; or ▪ Ciprofloxacin 500–750 mg PO bid; or ▪ Levofloxacin 500 mg PO daily; or ▪ Moxifloxacin 400 mg PO daily	Testing of susceptibility to clarithromycin and azithromycin is recommended **(BIII)** In ART-naïve patients, may consider withholding initiation of ART until after 2 weeks of MAC treatment to lessen drug interactions, reduce pill burden, and potentially lower occurrence of IRIS **(CIII)** NSAIDs may be used for patients who experience moderate to severe symptoms attributed to ART-associated IRIS **(CIII)** If immune reconstitution inflammatory syndrome (IRIS) symptoms persist, short term (4–8 weeks) of systemic corticosteroid (equivalent to 20–40 mg of prednisone) can be used **(CIII)**
	Chronic maintenance therapy (secondary prophylaxis) ▪ Same as treatment drugs and regimens Duration: Lifelong therapy **(AII)**, unless in patients with sustained immune recovery on ART **(BII)**		

TABLE 2. (*Continued*) Drug therapy for treatment and chronic maintenance therapy of AIDS-associated opportunistic infections in adults and adolescents

Opportunistic infection	Preferred therapy, duration of therapy, chronic maintenance	Alternative therapy	Other options/issues
Bacterial respiratory diseases	Preferred empiric outpatient therapy (oral) ▪ A beta-lactam plus a macrolide (azithromycin or clarithromycin) **(AII)** *Preferred beta-lactams*: high-dose amoxicillin or amoxicillin/clavulanate *Alternative beta-lactams*: cefpodoxime or cefuroxime	Alternative empiric outpatient therapy (oral) ▪ A beta-lactam plus doxycycline **(CIII)** *For penicillin-allergic patients or those with beta-lactam use in prior 3 months* ▪ A respiratory fluoroquinolone (levofloxacin 750 mg/day, gemifloxacin, or moxifloxacin) **(AII)**	Patients receiving macrolide for MAC prophylaxis should not receive macrolide monotherapy for empiric treatment of bacterial pneumonia Fluoroquinolones should be used with caution in patients where TB is suspected but is not being treated Empiric therapy with a macrolide alone is not routinely recommended, because of increasing pneumococcal resistance **(DIII)** Once the pathogen has been identified by a reliable microbiologic method, antibiotics should be directed at the pathogen **(BIII)** For patients begun on IV antibiotic therapy, switching to PO should be considered when patient is clinically improved and able to tolerate oral medications Chemoprophylaxis may be considered for patients with frequent recurrences of serious bacterial respiratory infections **(CIII)** Clinicians should be cautious of using antibiotics to prevent recurrences, because of the potential for developing drug resistance and drug toxicities
	Preferred empiric therapy for non-ICU inpatient ▪ A beta-lactam (IV) plus a macrolide **(AII)** *Preferred beta-lactams:* cefotaxime, ceftriaxone, or ampicillin-sulbactam	Alternative empiric therapy for non-ICU inpatient ▪ A beta-lactam (IV) plus doxycycline **(CIII)** *For penicillin-allergic patients or those with beta-lactam use in prior 3 months* ▪ An IV respiratory fluoroquinolone (levofloxacin 750 mg or moxifloxacin) **(AII)**	
	Preferred empiric ICU inpatient therapy ▪ A beta-lactam (IV) plus azithromycin IV **(AII)** or an IV respiratory fluoroquinolone (levofloxacin 750 mg or moxifloxacin) **(AII)** *Preferred beta-lactams*: cefotaxime, ceftriaxone, or ampicillin-sulbactam	Alternative empiric ICU therapy *For penicillin-allergic patients or those with beta-lactam use in prior 3 months* ▪ Aztreonam IV plus an IV respiratory fluoroquinolone **(BIII)**	
	Preferred empiric *Pseudomonas* therapy (if risks present) ▪ An antipneumococcal, antipseudomonal beta-lactam plus either ciprofloxacin or levofloxacin 750 mg/day **(BIII)** *Preferred beta-lactams*: piperacillin-tazobactam, cefepime, imipenem, or meropenem	Alternative empiric *Pseudomonas* therapy ▪ An antipneumococcal, antipseudomonal beta-lactam plus an aminoglycoside plus azithromycin **(BIII)** ▪ Above beta-lactam plus an aminoglycoside plus an antipneumococcal fluoroquinolone* **(BIII)** *For penicillin-allergic patients or those with beta-lactam use in prior 3 months* ▪ Replace the beta-lactam with aztreonam **(BIII)**	
	Preferred empiric methicillin-resistant *Staphylococcus aureus* (if risks present) ▪ Add vancomycin (possibly plus clindamycin) or linezolid alone to above **(BIII)**		

TABLE 2. (*Continued*) Drug therapy for treatment and chronic maintenance therapy of AIDS-associated opportunistic infections in adults and adolescents

Opportunistic infection	Preferred therapy, duration of therapy, chronic maintenance	Alternative therapy	Other options/issues
Bacterial enteric infections: Salmonellosis	Most specialists recommend treatment for all HIV-infected patients with salmonellosis due to the high risk of bacteremia in these patients **(BIII)** Preferred therapy for *Salmonella* gastroenteritis with or without symptomatic bacteremia ▪ Ciprofloxacin 500–750 mg PO bid (or 400 mg IV bid) **(AIII)** Duration for mild gastroenteritis with or without bacteremia ▪ If CD4+ count ≥200/μL: 7–14 days **(BIII)** ▪ If CD4+ count <200/μL: 2–6 weeks **(CIII)** ▪ If recurrent symptomatic septicemia – may need 6 months or more **(CIII)**	Alternative therapy for *Salmonella* gastroenteritis with or without symptomatic bacteremia ▪ Levofloxacin 750 mg or moxifloxacin **(BIII)** ▪ TMP-SMX PO or IV **(BIII)** – if susceptible ▪ Third generation cephalosporin such as ceftriaxone (IV) or cefotaxime (IV) **(BIII)** – if susceptible	The role of long-term secondary prophylaxis for patients with recurrent bacteremia is not well established. Must weigh the benefit against the risks of long-term antibiotic exposure
Bacterial enteric infections: Shigellosis	Preferred therapy for *Shigella* infection ▪ Fluoroquinolone IV or PO **(AIII)** Duration of therapy: *for gastroenteritis:* 3–7 days **(AIII)** *for bacteremia:* 14 days **(BIII)**	Alternative therapy depending on antibiotic susceptibility *For gastroenteritis* ▪ TMP-SMX DS 1 tab PO bid for 3–7 days **(BIII)**; or ▪ Azithromycin 500 mg PO on day 1, then 250 mg PO daily for 4 days **(BIII)**	Therapy is indicated both to shorten the duration of illness and to prevent spread of infection **(AIII)** *Shigella* infections acquired outside of United States have high rates of TMP-SMX resistance
Bacterial enteric infections: Campylobacteriosis	For mild disease Might withhold therapy unless symptoms persist for several days For mild-to-moderate disease ▪ Ciprofloxacin 500 mg PO bid **(BIII)**; or ▪ Azithromycin 500 mg PO daily **(BIII)** Consider addition of an aminoglycoside in bacteremic patients **(CIII)** Duration of therapy: ▪ Mild-to-moderate disease: 7 days **(BIII)** ▪ Bacteremia: at least 2 weeks **(BIII)**		There is an increasing rate of fluoroquinolone resistance Antimicrobial therapy should be modified based on susceptibility reports

TABLE 2. (*Continued*) Drug therapy for treatment and chronic maintenance therapy of AIDS-associated opportunistic infections in adults and adolescents

Opportunistic infection	Preferred therapy, duration of therapy, chronic maintenance	Alternative therapy	Other options/issues
Bartonella infections	Preferred therapy for bacillary angiomatosis, peliosis hepatis, bacteremia, and osteomyelitis ▪ Erythromycin 500 mg PO or IV qid **(AII)**; or ▪ Doxycycline 100 mg PO or IV q12h **(AII)** Duration of therapy: at least 3 months **(AII)** CNS infections and severe infections ▪ Doxycycline 100 mg PO or IV q12h +/- rifampin 300 mg PO or IV q12h **(AIII)** Duration of therapy: 4 months **(AII)** Long-term suppression ▪ With a macrolide or doxycycline for patients with relapse or reinfection as long as the CD4+ count remains <200 cells/μL **(AIII)**	Alternative therapy for bacillary angiomatosis infections, peliosis hepatis, bacteremia, and osteomyelitis ▪ Azithromycin 500 mg PO daily **(BIII)** ▪ Clarithromycin 500 mg PO bid **(BIII)**	Severe Jarisch-Herxheimer-like reaction can occur in the first 48 hours of treatment
Treponema pallidum infection (syphilis)	Preferred therapy early stage (primary, secondary, & early latent syphilis) ▪ Benzathine penicillin G 2.4 million units IM for 1 dose **(AII)** Preferred therapy late-latent disease (>1year or of unknown duration, CSF examination ruled out neurosyphilis) ▪ Benzathine penicillin G 2.4 million units IM weekly for 3 doses **(AIII)** Preferred therapy late-stage (tertiary – cardiovascular or gummatous disease) ▪ Rule out neurosyphilis before therapy with 3 doses of benzathine penicillin and obtain infectious diseases consultation to guide management **(AIII)** Preferred therapy neurosyphilis (including otic and ocular disease) ▪ Aqueous crystalline penicillin G, 18-24 million units per day, administered as 3–4 million units IV q4h or by continuous IV infusion for 10–14 days **(AII)** +/- benzathine penicillin G 2.4 million units IM weekly for 3 doses after completion of IV therapy **(CIII)**	Alternative therapy early stage (primary, secondary, and early latent syphilis) **(BIII)** *For penicillin-allergic patients:* ▪ Doxycycline 100 mg PO bid for 14 days **(BIII)**; or ▪ Ceftriaxone 1 g IM or IV daily for 8–10 days **(BIII)**; or ▪ Azithromycin 2 g PO for 1 dose **(CII)** Alternative therapy late-latent disease (without CNS involvement) *For penicillin-allergic patients:* ▪ Doxycycline 100 mg PO bid for 28 days **(BIII)** Alternative therapy neurosyphilis ▪ Procaine penicillin 2.4 million units IM daily plus probenecid 500 mg PO qid for 10–14 days **(BII)** +/- benzathine penicillin G 2.4 million units IM weekly for 3 doses after completion of above **(CIII)**; or *For penicillin-allergic patients*: ▪ Desensitization to penicillin is the preferred approach **(BIII)**; if not feasible, ▪ Ceftriaxone 2 grams IM or IV daily for 10–14 days **(CIII)**	The efficacy of non-penicillin alternatives has not been evaluated in HIV-infected patients and should be undertaken only with close clinical and serologic monitoring **(BIII)** Combination of procaine penicillin and probenecid is not recommended for patients with history of sulfa allergy **(DIII)** The Jarisch-Herxheimer reaction is an acute febrile reaction accompanied by headache and myalgias that might occur within the first 24 hours after therapy for syphilis

TABLE 2. (*Continued*) Drug therapy for treatment and chronic maintenance therapy of AIDS-associated opportunistic infections in adults and adolescents

Opportunistic infection	Preferred therapy, duration of therapy, chronic maintenance	Alternative therapy	Other options/issues
Candidiasis (mucosal)	Preferred therapy oropharyngeal candidiasis: initial episodes (7–14 day treatment) ▪ Fluconazole 100 mg PO daily **(AI)**; or ▪ Clotrimazole troches 10 mg PO 5 times daily **(BII)**; or ▪ Nystatin suspension 4–6 mL qid or 1–2 flavored pastilles 4–5 times daily **(BII)** ▪ Miconazole mucoadhesive tablet PO daily **(BII)**	Alternative therapy oropharyngeal candidiasis: initial episodes (7–14 day treatment) ▪ Itraconazole oral solution 200 mg PO daily **(BI)**; or ▪ Posaconazole oral solution 400 mg PO bid x 1, then 400 mg daily **(BI)**	Chronic or prolonged use of azoles might promote development of resistance Higher relapse rate of esophageal candidiasis with echinocandins than with fluconazole has been reported Patients with fluconazole refractory oropharyngeal or esophageal candidiasis who responded to echinocandin should be started on voriconazole or posaconazole for secondary prophylaxis until ART produces immune reconstitution **(CI)**
	Preferred therapy esophageal candidiasis (14–21 days) ▪ Fluconazole 100 mg (up to 400 mg) PO or IV daily **(AI)** ▪ Itraconazole oral solution 200 mg PO daily **(AI)**	Alternative therapy esophageal candidiasis (14–21 days) ▪ Voriconazole 200 mg PO or IV bid **(BI)** ▪ Posaconazole 400 mg PO bid **(BI)** ▪ Caspofungin 50 mg IV daily **(BI)** ▪ Micafungin 150 mg IV daily **(BI)** ▪ Anidulafungin 100 mg IV x 1, then 50 mg IV daily **(BI)** ▪ Amphotericin B deoxycholate 0.6 mg/kg IV daily **(BI)**	Suppressive therapy is usually not recommended **(DIII)** unless patients have frequent or severe recurrences. If decision is to use suppressive therapy: Oropharyngeal candidiasis ▪ Fluconazole 100 mg PO tiw **(BI)** ▪ Itraconazole oral solution 200 mg PO daily **(CI)** Esophageal candidiasis ▪ Fluconazole 100–200 mg PO daily **(BI)** ▪ Posaconazole 400 mg PO bid **(BII)**
	Preferred therapy uncomplicated vulvovaginal candidiasis ▪ Oral fluconazole 150 mg for 1 dose **(AII)** ▪ Topical azoles (clotrimazole, butoconazole, miconazole, tioconazole, or terconazole) for 3–7 days **(AII)**	Alternative therapy uncomplicated vulvovaginal candidiasis ▪ Itraconazole oral solution 200 mg PO daily for 3-7 days **(BII)**	Vulvovaginal candidiasis ▪ Fluconazole 150 mg PO once weekly **(CII)** ▪ Daily topical azole **(CII)**
	Preferred therapy fluconazole-refractory oropharyngeal candidiasis or esophageal candidiasis ▪ Itraconazole oral solution ≥200 mg PO daily **(AII)** ▪ Posaconazole oral solution 400 mg PO bid **(AII)**	Alternative therapy fluconazole-refractory oropharyngeal candidiasis or esophageal candidiasis ▪ Amphotericin B deoxycholate 0.3 mg/kg IV daily **(BII)** ▪ Lipid formulation of amphotericin B 3–5 mg/kg IV daily **(BII)** ▪ Anidulafungin 100 mg IV x 1, then 50 mg IV daily **(BII)** ▪ Caspofungin 50 mg IV daily **(CII)** ▪ Micafungin 150 mg IV daily **(CII)** ▪ Voriconazole 200 mg PO or IV bid **(CIII)** *Fluconazole-refractory oropharyngeal candidiasis (not esophageal)* ▪ Amphotericin B oral suspension 100 mg/mL (not available in U.S.) – 1 mL PO qid **(CIII)**	
	Preferred therapy complicated (severe or recurrent) vulvovaginal candidiasis ▪ Fluconazole 150 mg q72h x 2-3 doses **(AII)** ▪ Topical antifungal ≥7 days **(AII)**		

TABLE 2. (*Continued*) Drug therapy for treatment and chronic maintenance therapy of AIDS-associated opportunistic infections in adults and adolescents

Opportunistic infection	Preferred therapy, duration of therapy, chronic maintenance	Alternative therapy	Other options/issues
Cryptococcal meningitis	Preferred induction therapy ▪ Amphotericin B deoxycholate 0.7 mg/kg IV daily plus flucytosine 100 mg/kg PO daily in 4 divided doses for at least 2 weeks **(AI)**; or ▪ Lipid formulation amphotericin B 4–6 mg/kg IV daily (consider for persons who have renal dysfunction on therapy or have high likelihood of renal failure) plus flucytosine 100 mg/kg PO daily in 4 divided doses for at least 2 weeks **(AII)**	Alternative induction therapy ▪ Amphotericin B (deoxycholate or lipid formulation, dose as preferred therapy) plus fluconazole 400 mg PO or IV daily **(BII)** ▪ Amphotericin B (deoxycholate or lipid formulation, dose as preferred therapy) alone **(BII)** ▪ Fluconazole 400–800 mg/day (PO or IV) plus flucytosine 100 mg/kg PO daily in 4 divided doses for 4–6 weeks **(CII)** – for persons unable to tolerate or unresponsive to amphotericin B	Addition of flucytosine to amphotericin B has been associated with more rapid sterilization of CSF and decreased risk for subsequent relapse Patients receiving flucytosine should have blood levels monitored; peak level 2 hours after dose should not exceed 75 μg/mL. Dosage should be adjusted in patients with renal insufficiency. Opening pressure should always be measured when a lumbar puncture (LP) is performed **(AII)**. Repeated LPs or CSF shunting are essential to effectively manage increased intracranial pressure **(BIII)**.
	Preferred consolidation therapy (after at least 2 weeks of successful induction – defined as significant clinical improvement & negative CSF culture) ▪ Fluconazole 400 mg PO daily for 8 weeks **(AI)**	Alternative consolidation therapy ▪ Itraconazole 200 mg PO bid for 8 weeks **(BI)**, or until CD4+ count ≥200 cells/μL for >6 months as a result of ART **(BII)**.	
	Preferred maintenance therapy ▪ Fluconazole 200 mg PO daily **(AI)** lifelong or until CD4+ count ≥200 cells/μL for >6 months as a result of ART **(BII)**	Alternative maintenance therapy ▪ Itraconazole 200 mg PO daily lifelong unless immune reconstitution as a result of potent ART – for patients intolerant of or who failed fluconazole **(BI)**	

TABLE 2. (*Continued*) Drug therapy for treatment and chronic maintenance therapy of AIDS-associated opportunistic infections in adults and adolescents

Opportunistic infection	Preferred therapy, duration of therapy, chronic maintenance	Alternative therapy	Other options/issues
Histoplasma capsulatum infections	Preferred therapy for moderately severe to severe disseminated disease *Induction therapy* (for 2 weeks or until clinically improved) ▪ Liposomal amphotericin B at 3 mg/kg IV daily **(AI)** *Maintenance therapy* ▪ Itraconazole 200 mg PO tid for 3 days, then bid **(AII)** Preferred therapy for less severe disseminated disease *Induction and maintenance therapy* ▪ Itraconazole 200 mg PO tid for 3 days, then 200 mg PO bid **(AII)** Duration of therapy: at least 12 months Preferred therapy for meningitis *Induction therapy* (4–6 weeks) ▪ Liposomal amphotericin B 5 mg/kg/day **(AII)** *Maintenance therapy* ▪ Itraconazole 200 mg PO bid-tid for ≥1 year and until resolution of abnormal CSF findings **(AII)** Preferred therapy for long term suppression therapy In patients with severe disseminated or CNS infection **(AII)** and in patients who relapse despite appropriate therapy **(CIII)** ▪ Itraconazole 200 mg PO daily	Alternative therapy moderately severe to severe disseminated disease *Induction therapy* (for 2 weeks or until clinically improved) ▪ Amphotericin B deoxycholate 0.7 mg/kg IV daily **(BI)** ▪ Amphotericin B lipid complex 5 mg/kg IV daily **(CIII)** *Maintenance therapy* same as "Preferred therapy"	Itraconazole levels should be obtained in all patients to ensure adequate absorption **(AIII)**. Serum concentrations of itraconazole + hydroxyitraconazole should be >1 μg/mL Itraconazole oral solution is preferred over capsule by certain specialists because of improved absorption Acute pulmonary histoplasmosis in HIV-infected patients with CD4+ count >300 cells/μL should be managed as non-immunocompromised host **(AIII)**

TABLE 2. (*Continued*) Drug therapy for treatment and chronic maintenance therapy of AIDS-associated opportunistic infections in adults and adolescents

Opportunistic infection	Preferred therapy, duration of therapy, chronic maintenance	Alternative therapy	Other options/issues
Coccidioidomycosis	Preferred therapy for mild infections (focal pneumonia or positive coccidiodal serologic test alone) ▪ Fluconazole 400 mg PO daily **(BII)**; or ▪ Itraconazole 200 mg PO tid x 3 days, then 200 mg bid **(BII)**		Certain patients with meningitis may develop hydrocephalus and require CSF shunting Therapy should be continued indefinitely for patients with diffuse pulmonary or disseminated diseases as relapse can occur in 25%–33% in HIV-negative patients **(AIII)**
	Preferred therapy for severe, nonmeningeal infection (diffuse pulmonary or severely ill patients with extrathoracic disseminated disease): acute phase ▪ Amphotericin B deoxycholate 0.7–1.0 mg/kg IV daily **(AII)** ▪ Lipid formulation amphotericin B 4–6 mg/kg IV daily **(AIII)** Duration of therapy: until clinical improvement, then switch to azole	Alternative therapy for severe nonmeningeal infection (diffuse pulmonary or disseminated disease): acute phase ▪ Certain specialists add triazole to amphotericin B therapy and continue triazole once amphotericin B is stopped **(BIII)**	Therapy should be lifelong in patients with meningeal infections as relapse occurred in 80% of HIV-infected patients after discontinuation of triazole therapy **(AII)** Case reports of successful therapy with voriconazole and posaconazole are available.
	Preferred therapy for meningeal infections ▪ Fluconazole 400–800 mg PO or IV daily **(AII)**	Alternative therapy for meningeal infections ▪ Itraconazole 200 mg PO tid x 3 days, then 200 mg PO bid **(BII)** ▪ Intrathecal amphotericin B when triazole antifungals are not effective **(AIII)**	
	Maintenance therapy (for all cases) ▪ Fluconazole 400 mg PO daily **(AII)**; or ▪ Itraconazole 200 mg PO bid **(AII)**		
Aspergillosis, invasive	Preferred therapy ▪ Voriconazole 6 mg/kg q12h x 1 day, then 4 mg/kg q12h IV **(BIII)**, followed by voriconazole PO 200 mg q12h after clinical improvement Duration of therapy: until CD4+ count >200 cells/μL and with evidence of clinical response	Alternative therapy ▪ Amphotericin B deoxycholate 1 mg/kg/day IV **(AIII)**; or ▪ Lipid formulation of amphotericin B 5 mg/kg/day IV **(AIII)** ▪ Caspofungin 70 mg IV x 1, then 50 mg IV daily **(BII)** ▪ Posaconazole 400 mg bid PO **(BII)**	Potential for significant pharmacokinetic interactions between PIs or NNRTIs with voriconazole; it should be used cautiously in these situations. Consider therapeutic drug monitoring and dosage adjustment if necessary.

TABLE 2. (*Continued*) Drug therapy for treatment and chronic maintenance therapy of AIDS-associated opportunistic infections in adults and adolescents

Opportunistic infection	Preferred therapy, duration of therapy, chronic maintenance	Alternative therapy	Other options/issues
Cytomegalovirus (CMV) disease	Preferred therapy for CMV retinitis *For immediate sight-threatening lesions* ▪ Ganciclovir intraocular implant + valganciclovir 900 mg PO (bid for 14–21 days, then once daily) **(AI)** ▪ One dose of intravitreal ganciclovir may be administered immediately after diagnosis until ganciclovir implant can be placed **(CIII)** *For small peripheral lesions* ▪ Valganciclovir 900 mg PO bid for 14–21 days, then 900 mg PO daily **(BII)**	Alternative therapy for CMV retinitis ▪ Ganciclovir 5 mg/kg IV q12h for 14–21 days, then 5 mg/kg IV daily **(AI)**; or ▪ Ganciclovir 5 mg/kg IV q12h for 14–21 days, then valganciclovir 900 mg PO daily **(AI)**; or ▪ Foscarnet 60 mg/kg IV q8h or 90 mg/kg IV q12h for 14–21 days, then 90–120 mg/kg IV q24h **(AI)**; or ▪ Cidofovir 5 mg/kg/week IV for 2 weeks, then 5 mg/kg every other week with saline hydration before and after therapy and probenecid 2 g PO 3 hours before the dose followed by 1 g PO 2 hours after the dose, and 1 g PO 8 hours after the dose (total of 4 g) **(AI)** Note: This regimen should be avoided in patients with sulfa allergy because of cross hypersensitivity with probenecid	The choice of initial therapy for CMV retinitis should be individualized, based on location and severity of the lesion(s), level of immunosuppression, and other factors such as concomitant medications and ability to adhere to treatment **(AIII)** Initial therapy in patients with CMV retinitis, esophagitis, colitis, and pneumonitis should include initiation or optimization of ART **(BIII)** In patients with CMV neurological disease, localized morbidity might occur because of IRIS, a brief delay in initiation of ART until clinical improvement might be prudent **(CIII)** Maintenance therapy for CMV retinitis can be safely discontinued in patients with inactive disease and sustained CD4+ count (>100 cells/mm^3 for ≥3–6 months); consultation with ophthalmologist is advised **(BII)** Patients with CMV retinitis who discontinued maintenance therapy should undergo regular eye examination, optimally every 3 months, for early detection of relapse or immune recovery uveitis (IRU) **(AIII)** IRU might develop in the setting of immune reconstitution. Treatment of IRU: periocular corticosteroid or short courses of systemic steroid
	Preferred chronic maintenance therapy (secondary prophylaxis) for CMV retinitis ▪ Valganciclovir 900 mg PO daily **(AI)**; or ▪ Ganciclovir implant (may be replaced every 6–8 months if CD4+ count remains <100 cells/μL) + valganciclovir 900 mg PO daily until immune recovery **(BIII)**	Alternative chronic maintenance (secondary prophylaxis) for CMV retinitis ▪ Ganciclovir 5 mg/kg IV 5–7 times weekly **(AI)**; or ▪ Foscarnet 90–120 mg/kg body weight IV once daily **(AI)**; or ▪ Cidofovir 5 mg/kg body weight IV every other week with saline hydration and probenecid as above **(AI)**	
	Preferred therapy for CMV esophagitis or colitis ▪ Ganciclovir IV or foscarnet IV for 21–28 days or until resolution of signs and symptoms **(BII)** ▪ Oral valganciclovir may be used if symptoms are not severe enough to interfere with oral absorption **(BII)** ▪ Maintenance therapy is usually not necessary, but should be considered after relapses **(BII)**		
	Preferred therapy CMV pneumonitis ▪ Treatment should be considered in patients with histologic evidence of CMV pneumonitis and who do not respond to treatment of other pathogens **(AIII)** ▪ The role of maintenance therapy has not been established **(CIII)**		
	Preferred therapy CMV neurological disease *Treatment should be initiated promptly* ▪ Combination of ganciclovir IV + foscarnet IV to stabilize disease and maximize response, continue until symptomatic improvement **(BII)** ▪ Maintenance therapy (with valganciclovir PO + IV foscarnet) should be continued for life unless evidence of immune recovery is evident **(BII)**		

TABLE 2. (*Continued*) Drug therapy for treatment and chronic maintenance therapy of AIDS-associated opportunistic infections in adults and adolescents

Opportunistic infection	Preferred therapy, duration of therapy, chronic maintenance	Alternative therapy	Other options/issues
Herpes simplex virus (HSV) disease	Preferred therapy for orolabial lesions and initial or recurrent genital HSV ▪ Valacyclovir 1 g PO bid, famciclovir 500 mg PO bid, or acyclovir 400 mg PO tid **(AI)** Duration of therapy: ▪ Orolabial HSV: 5–10 days **(AII)** ▪ Genital HSV: 5–14 days **(AI)** Preferred therapy for severe mucocutaneous HSV infections ▪ Initial therapy acyclovir 5 mg/kg IV q8h **(AII)** ▪ After lesions began to regress, change to PO therapy as above **(AI)**. Continue therapy until lesions have completely healed.		
	Preferred therapy for acyclovir-resistant mucocutaneous HSV infections ▪ Foscarnet 80–120 mg/kg/day IV in 2–3 divided doses until clinical response **(AI)**	Alternative therapy for acyclovir-resistant mucocutaneous HSV infections **(CIII)** ▪ Topical trifluridine ▪ Topical cidofovir ▪ Topical imiquimod Duration of therapy: 21–28 days or longer	Topical formulations of neither trifluridine nor cidofovir are commercially available in the U.S. Extemporaneous compounding of topical products can be prepared using trifluridine ophthalmic solution and the intravenous formulation of cidofovir
	Preferred therapy for HSV encephalitis ▪ Acyclovir 10 mg/kg IV q8h for 21 days **(AII)** Suppressive therapy (For patients with frequent or severe recurrences of genital herpes) **(AI)** ▪ Valacyclovir 500 mg PO bid **(AI)** ▪ Famciclovir 500 mg PO bid **(AI)** ▪ Acyclovir 400 mg PO bid **(AI)**		
HHV-6 infection	If HHV-6 has been identified as cause of disease in HIV-infected patients, use same drugs and doses as treatment for CMV disease **(CIII)** ▪ Ganciclovir (or valganciclovir) ▪ Foscarnet		

TABLE 2. (*Continued*) Drug therapy for treatment and chronic maintenance therapy of AIDS-associated opportunistic infections in adults and adolescents

Opportunistic infection	Preferred therapy, duration of therapy, chronic maintenance	Alternative therapy	Other options/issues
Varicella zoster virus (VZV) disease	Varicella (chickenpox) *Uncomplicated cases* ▪ Acyclovir (20 mg/kg body weight up to a maximum of 800 mg PO 5x daily), valacyclovir 1,000 mg PO tid, or famciclovir 500 mg PO tid x 5–7 days **(AII)** *Severe or complicated cases* ▪ Acyclovir 10–15 mg/kg IV q8h x 7–10 days **(AIII)** ▪ May switch to oral acyclovir, famciclovir, or valacyclovir after defervescence if no evidence of visceral involvement is evident **(AIII)** Herpes zoster (shingles) *Acute localized dermatomal* ▪ Valacyclovir 1g tid or famciclovir 500 mg tid, or acyclovir 800 mg PO 5x daily x 7–10 days **(AII)**, longer duration should be considered if lesions are slow to resolve *Extensive cutaneous lesion or visceral involvement* ▪ Acyclovir 10–15 mg/kg IV q8h until clinical improvement is evident **(AII)** ▪ Switch to oral therapy (valacyclovir 1,000 mg tid or famciclovir 500 mg tid, or acyclovir 800 mg PO 5x daily) after clinical improvement is evident, to complete a 10–14 day course **(AIII)** Progressive outer retinal necrosis (PORN) ▪ Ganciclovir 5 mg/kg IV q12h, plus foscarnet 90 mg/kg IV q12h, plus ganciclovir 2 mg/0.05mL intravitreal twice weekly, and/or foscarnet 1.2 mg/0.05mL intravitreal twice weekly **(AIII)** ▪ Optimization of ART **(AIII)** Acute retinal necrosis (ARN) ▪ Acyclovir 10 mg/kg IV q8h x 10–14 days, followed by valacyclovir 1,000 mg PO tid x 6 weeks **(AIII)**	Infection caused by acyclovir-resistant VZV ▪ Foscarnet 90 mg/kg IV q12h **(AII)**	Involvement of an experienced ophthalmologist with management of VZV retinitis is strongly recommended **(AIII)** Corticosteroid therapy for herpes zoster is not recommended **(DIII)**

TABLE 2. (*Continued*) Drug therapy for treatment and chronic maintenance therapy of AIDS-associated opportunistic infections in adults and adolescents

Opportunistic infection	Preferred therapy, duration of therapy, chronic maintenance	Alternative therapy	Other options/issues
HHV-8 diseases (*Kaposi's Sarcoma [KS], primary effusion lymphoma [PEL], multicentric Castleman's disease [MCD],)*	Initiation or optimization of ART should be done for all patients with KS, PEL, or MCD **(BII)** Preferred therapy for visceral KS **(BII),** disseminated cutaneous KS **(CIII)**, and PEL **(BIII)** ▪ Chemotherapy + ART **(BII)** ▪ Oral valganciclovir or IV ganciclovir might be useful as adjunctive therapy in PEL **(BII)** Preferred therapy for MCD ▪ Valganciclovir 900 mg PO bid **(BII)**; or ▪ Ganciclovir 5 mg/kg IV q12h **(BII)**	Alternative therapy for MCD Rituximab, 375 mg/m^2 given weekly x 4–8 weeks, may be an alternative to antiviral therapy **(BII)**	
Human papillomavirus disease	Treatment of condyloma acuminata (genital warts) Patient-applied therapy ▪ Podofilox 0.5% solution or 0.5% gel – apply to all lesions bid x 3 consecutive days, followed by 4 days of no therapy, repeat weekly for up to 4 cycles **(BIII)**; or ▪ Imiquimod 5% cream – apply to lesion at bedtime and remove in the morning on 3 nonconsecutive nights weekly for up to 16 weeks. Each treatment should be washed with soap and water 6–10 hours after application **(BII)**	Provider-applied therapy ▪ Cryotherapy (liquid nitrogen or cryoprobe) – apply until each lesion is thoroughly frozen; repeat every 1–2 weeks. Some providers allow the lesion to thaw, then freeze a 2nd time in each session **(BIII)**. ▪ Trichloroacetic acid or bicloroacetic acid cauterization – 80%–90% aqueous solution, apply to each lesion, repeat weekly for 3–6 weeks **(BIII)** ▪ Surgical excision **(BIII)** or laser surgery **(CIII)** ▪ Podophyllin resin 10%–25% suspension in tincture of benzoin – apply to all lesions, then wash off a few hours later, repeat weekly for 3–6 weeks **(CIII)**	Intralesional interferon-alpha is usually not recommended because of high cost, difficult administration, and potential for systemic side effects **(DIII)** The rate of recurrence of genital warts is high, despite treatment

TABLE 2. (*Continued*) Drug therapy for treatment and chronic maintenance therapy of AIDS-associated opportunistic infections in adults and adolescents

Opportunistic infection	Preferred therapy, duration of therapy, chronic maintenance	Alternative therapy	Other options/issues
Hepatitis B virus (HBV) disease	Therapy for patients who require ART ▪ Patients should be treated with agents active against both HIV and HBV or with agents with independent activity against each virus **(CIII)** ▪ Consider tenofovir + emtricitabine as part of HIV and HBV regimen **(CIII)** *Lamivudine or emtricitabine-naïve patients* ▪ [Lamivudine 150 mg PO bid (or 300 mg PO daily) or emtricitabine 200 mg PO daily] + tenofovir (TDF) 300 mg PO daily **(CIII)** (+ additional agent[s] active against HIV) *Lamivudine or emtricitabine-experienced patients with detectable HBV DNA (assume lamivudine-resistance)* ▪ *If not on TDF*: Add TDF 300 mg PO daily as part of an ART regimen + lamivudine or emtricitabine **(CIII)**; or ▪ Adefovir 10 mg PO daily + lamivudine or emtricitabine + other combination ART **(BII)**; or ▪ Entecavir 1 mg PO daily can be considered in patients with complete HIV suppression (while on ART) who do not demonstrate YMDD (M204V/I) motif mutations in HBV DNA **(CIII)** Duration of therapy: Because of the high rates of relapse, certain specialists recommend continuing therapy indefinitely **(CIII)**	Treatment for patients who do not require ART ▪ Use agents with sole activity against HBV and with the least potential of selecting HIV resistance mutations **(BIII)** ▪ Consider early initiation of ART, especially for patients with high HBV DNA *For patients with CD4+ count >350 cells/μL, HBeAg (-), HBV DNA >2,000 IU/mL (>20,000 copies/mL)* ▪ Adefovir 10 mg PO daily **(CIII)** *For patients with CD4+ count >350 cells/μL, HBeAg (+), HBV DNA >20,000 IU/mL (>200,000 copies/mL), and elevated ALT* ▪ Peginterferon alfa-2a 180 μg SQ weekly **(CIII)** x 48 weeks – with careful follow-up of HBeAg conversion	Emtricitabine, entecavir, lamivudine, or tenofovir should not be used for the treatment of HBV infection in patients who are not receiving combination ART **(EII)** Among patients coinfected with HIV, HBV, and HCV, consideration of starting ART should be the first priority. If ART is not required, an interferon-based regimen, which suppresses both HCV & HBV, should be considered **(CIII)** If IFN-based treatment for HCV has failed, treatment of chronic HBV with nucleoside or nucleotide analogs is recommended **(CIII)** Cross-resistance to emtricitabine or telbivudine should be assumed in patients with suspected or proven 3TC resistance When changing ART regimens, continue agents with anti-HBV activity because of the risk of IRIS If anti-HBV therapy is discontinued and a flare occurs, therapy should be reinstituted, as it can be potentially life saving **(BIII)**
Hepatitis C virus (HCV) disease	Genotype 1, 4, 5, or 6 **(AI)** ▪ Peginterferon alfa-2a 180 μg SQ weekly, or ▪ Peginterferon alfa-2b 1.5 mg/kg SQ weekly + ▪ Ribavirin PO (wt-based dosing) **(AII)** <75 kg: 600 mg qAM and 400 mg qPM; ≥75 kg: 600 mg qAM and 600 mg qPM Genotype 2 or 3 **(AI)** ▪ Peginterferon alfa-2a 180μg SQ weekly, or ▪ Peginterferon alfa-2b 1.5 mg/kg SQ weekly + ▪ Ribavirin (fixed dose) PO 400 mg qAM and 400 mg qPM Duration of therapy: ▪ 48 weeks – genotypes 1 or 4, 5 or 6 **(AI)** and genotypes 2 and 3 **(BII)** ▪ At least 24 weeks – treatment of acute HCV infection (<6 months from HCV exposure) **(BIII)**	In patients for whom ribavirin is contraindicated (e.g. unstable cardiopulmonary disease, pre-existing anemia unresponsive to erythropoietin, renal failure, or hemoglobinopathy) ▪ Peginterferon alfa-2a 180 μg SQ weekly **(AII)**, or ▪ Peginterferon alfa-2b 1.5 μg/kg SQ weekly **(AII)** In patients with decompensated liver disease ▪ Liver transplantation if feasible **(CIII)**	For patients with CD4+ count <200 cells/μL, initiation of ART may be considered before HCV treatment **(CIII)** Didanosine + ribavirin may lead to increased mitochondrial toxicities; concomitant use is contraindicated **(EI)**. HCV therapy is not recommended in patients with hepatic decompensation. Liver transplantation, if feasible, should be the primary treatment option **(CIII)**. Interferon is abortifacient in high doses and ribavirin is teratogenic. HCV treatment is not recommended in pregnant women or women who are not willing to use birth control **(EIII)**.

TABLE 2. (*Continued*) Drug therapy for treatment and chronic maintenance therapy of AIDS-associated opportunistic infections in adults and adolescents

Opportunistic infection	Preferred therapy, duration of therapy, chronic maintenance	Alternative therapy	Other options/issues
Progressive multifocal leukoencephalopathy (JC virus infections)	Initiate antiretroviral therapy in ART-naïve patients **(AII)** Optimize ART in patients who develop PML in phase of HIV viremia on antiretroviral therapy **(AIII)**		Some patients might experience a remission after initiation of ART. Although their neurological deficits frequently persist, disease progression remits. Corticosteroids may be used in patients with progressive clinical deficits and neuroimaging features suggesting inflammatory disease (e.g., edema, swelling, and contrast enhancement) as a result of initiating ART **(BIII)**
Geographic opportunistic infections of specific consideration			
Malaria			
Uncomplicated malaria from *Plasmodium falciparum* or unknown malaria species	Preferred therapy for chloroquine-sensitive infection (north of the Panama Canal) ▪ Chloroquine phosphate 1,000 mg PO (=600 mg chloroquine base) once, then 500 mg PO (=300 mg chloroquine base) at 6, 24, and 48 hours ▪ Total dose = chloroquine phosphate 2,500 mg	Alternative therapy for chloroquine-sensitive infection (north of the Panama Canal) No alternative listed	Treatment recommendations for HIV-infected patients are the same as HIV non-infected patients. For most updated treatment recommendations for specific region, clinicians should refer to the following web link: http://www.cdc.gov/malaria/ or call the CDC Malaria Hotline: 770-488-7788 - M-F 8 AM-4:30 PM ET 770-488-7100 - after hours
	Preferred therapy for chloroquine-resistant infections (all other malaria areas or unknown region) ▪ Atovaquone-proguanil (250 mg/100 mg) – 4 tablet PO daily x 3 days	Alternative therapy for chloroquine-resistant infections (all other malaria areas or unknown region) ▪ Mefloquine 750 mg PO x 1, then 500 mg administered 12 hrs later, total dose = 1,250 mg ▪ Quinine sulfate 650 mg PO q8h x 3 days (infections acquired outside of southeast Asia) to 7 days (infections acquired in southeast Asia) + (doxycycline 100 mg PO q12h x 7 days or clindamycin 20 mg base/kg/day (in 3 divided doses) PO x 7 days)	
Severe malaria from all regions	Preferred therapy ▪ Quinidine gluconate 10 mg/kg IV over 1–2 hours, then 0.02 mg/kg/min infusion (quinidine 6.25 mg base/kg IV over 1–2 hours, then 0.0125 mg/kg/min) for ≥24 hours with cardiac monitoring + ▪ Doxycycline 100 mg PO or IV q12h x 7 days; or ▪ Clindamycin 20 mg base/kg/day (in 3 divided doses) PO or 10 mg base/kg loading dose IV followed by 5 mg base/kg IV q8h; switch to PO clindamycin (dose as above) as soon as patient can take PO medication - for a total course of 7 days	Alternative therapy ▪ Artesunate 2.4 mg/kg IV bolus at 0, 12, and 24 hours, then daily Duration of therapy: 7 days for Southeast Asia and Oceania and 3 days for other areas When able to take PO, switch to: ▪ Atovaquone-proquanil, mefloquine, or doxycycline (doses as listed above)	Intravenous artesunate is available from CDC quarantine stations (CDC Malaria Hotline 770-488-7788)

TABLE 2. (*Continued*) Drug therapy for treatment and chronic maintenance therapy of AIDS-associated opportunistic infections in adults and adolescents

Opportunistic infection	Preferred therapy, duration of therapy, chronic maintenance	Alternative therapy	Other options/issues
Malaria from: *P. vivax* *P. ovale* *P. malariae*	All regions use the following regimens (except for Papua New Guinea and Indonesia, in which case treat as for chloroquine-resistant *P. falciparum* malaria as above) ▪ Chloroquine phosphate 1000 mg PO x 1, then 500 mg PO at 6, 24, and 48 hours, total dose = 2,500 mg; then ▪ Anti-relapse therapy (after checking G6PD status): primaquine 30 mg base PO daily x 14 days		G6PD status should be checked before initiation of primaquine
Penicilliosis	Acute infection in severely ill patients ▪ Amphotericin B deoxycholate 0.6 mg/kg/day IV for 2 weeks; followed by itraconazole 400 mg PO daily for 10 weeks **(AII)** Mild disease ▪ Itraconazole 400 mg PO daily for 8 weeks **(BII)** Chronic maintenance therapy (secondary prophylaxis) ▪ Itraconazole 200 mg PO daily **(AI)**		ART should be administered according to standard of care in the community; consideration should be given to simultaneously initiating ART and treatment for penicilliosis **(CIII)**
Leishmaniasis, visceral	Preferred therapy for initial infection ▪ Liposomal amphotericin B or amphotericin B lipid complex **(AII)** 2–4 mg/kg IV daily x 10 days; or interrupted schedule (e.g., 4 mg/kg on days 1–5, 10, 17, 24, 31, 38) to achieve total dose of 20–60 mg/kg **(BII)**	Alternative therapy for initial infection ▪ Amphotericin B deoxycholate 0.5–1.0 mg/kg IV daily for total dose of 1.5–2.0 grams **(BII)**; or ▪ Sodium stibogluconate (pentavalent antimony) **(AII)** 20 mg/kg body weight IV or IM daily for 3–4 weeks. (Contact the CDC Drug Service at 404-639-3670 or drugservice@cdc.gov)	ART should be initiated or optimized **(AII)** Parenteral paromomycin has been proven effective in HIV-negative patients in India - may be available as an alternative in India in the future **(BI)**
	Preferred chronic maintenance therapy (secondary prophylaxis) – especially in patients with CD4+ count <200 cells/μL ▪ Liposomal amphotericin B 4 mg/kg every 2–4 weeks **(AII)**	Alternative chronic maintenance therapy (secondary prophylaxis) ▪ Amphotericin B Lipid Complex **(AII)** 3–4 mg/kg every 2–4 weeks **(AII)** ▪ Sodium stibogluconate 20 mg/kg IV or IM every 4 weeks **(AII)**	Alternative regimens for treatment failure Miltefosine 100 mg PO daily for 4 weeks (available in Europe via compassionate use) **(CIII)**
Leishmaniasis, cutaneous	Preferred therapy for acute infection ▪ Liposomal amphotericin B 2–4 mg/kg IV daily for 10 days or interrupted schedule (e.g., 4 mg/kg on days 1–5, 10, 17, 24, 31, 38) to achieve total dose of 20–60 mg/kg **(BIII)**; or ▪ Sodium stibogluconate 20 mg/kg IV or IM daily for 3–4 weeks **(BIII)**	Alternative therapy for acute infection Choice dependent on species of *Leishmania* Other options include oral miltefosine, topical paromomycin, intralesional pentavalent antimony, and local heat therapy	

TABLE 2. (*Continued*) Drug therapy for treatment and chronic maintenance therapy of AIDS-associated opportunistic infections in adults and adolescents

Opportunistic infection	Preferred therapy, duration of therapy, chronic maintenance	Alternative therapy	Other options/issues
Chagas disease (American trypanosomiasis)	Preferred therapy for acute, early chronic, and reactivated disease ▪ Benznidazole 5–8 mg/kg/day PO in 2 divided doses for 30–60 days **(BIII)** (not commercially available in the U.S., contact the CDC Drug Service at 404-639-3670 or drugservice@cdc.gov)	Alternative therapy ▪ Nifurtimox 8–10 mg/kg/day PO for 90–120 days **(CIII)** (Contact the CDC Drug Service at 404-639-3670 or drugservice@cdc.gov)	Duration of therapy has not been studied in HIV-infected patients Initiation or optimization of ART in patients undergoing treatment for Chagas disease, once the patient is clinically stable **(AIII)**
Isospora belli infection	Preferred therapy for acute infection: ▪ TMP-SMX **(AI)** (160 mg/800 mg) PO (or IV) qid for 10 days **(AII);** or ▪ TMP-SMX (160 mg/800 mg) PO (or IV) bid for 7–10 days **(BI)** ▪ May increase daily dose and/or duration (up to 3–4 weeks) if symptoms worsen or persist **(BIII)**	Alternative therapy for acute infection ▪ Pyrimethamine 50–75 mg PO daily plus leucovorin 10–25 mg PO daily **(BIII)**; or ▪ Ciprofloxacin 500 mg PO bid x 7 days **(CI)** – as a second line alternative	Fluid and electrolyte management in patients with dehydration **(AIII)** Nutritional supplementation for malnourished patients **(AIII)** Immune reconstitution with ART may result in fewer relapses **(AIII)**
	Preferred chronic maintenance therapy (secondary prophylaxis) In patients with CD4+ count <200/μL, ▪ TMP-SMX (160 mg/800 mg) PO tiw **(AI)**	Alternative chronic maintenance therapy (secondary prophylaxis) ▪ TMP-SMX (160 mg/800 mg) PO daily or (320 mg/1600 mg) tiw **(BIII)** ▪ Pyrimethamine 25 mg PO daily + leucovorin 5–10 mg PO daily **(BIII)** ▪ Ciprofloxacin 500 mg tiw **(CI)** – as a second line alternative	

ART = antiretroviral therapy; bid = twice a day; biw = twice weekly; g = gram; IM = intramuscular; IV = intravenous; μg = microgram; mg = milligram; PO = oral; qAM = every morning; qid = four times a day; q'n'h = every 'n' hour; qPM = every evening; SQ = subcutaneous; tid = three times daily, tiw = three times weekly

TABLE 3. Recommended doses of first-line antituberculosis drugs for adults*

Drug	Daily	2x/wk (not recommended for patients with CD4+ count <100 cells/μL)	3x/wk
Isoniazid	5 mg/kg (usual dose 300 mg)	15 mg/kg (usual dose 900 mg)	15 mg/kg (usual dose 900 mg)
Rifampin [NOTE: rifampin is not recommended in patients receiving HIV protease inhibitor(s) (PI) or the CCR5 antagonist maraviroc]	10 mg/kg (usual dose 600 mg)	10 mg/kg (usual dose 600 mg)	10 mg/kg (usual dose 600 mg)
Rifabutin (w/o HIV PIs or NNRTI§)	5 mg/kg (usual dose 300 mg)	5 mg/kg (usual dose 300 mg)	5 mg/kg (usual dose 300 mg)
w/ HIV protease inhibitors	150 mg†	Not recommended†	150 mg†
w/ efavirenz	450–600 mg	450–600 mg	450–600 mg
Streptomycin/amikacin/ kanamycin	15 mg/kg	25 mg/kg	25 mg/kg
Pyrazinamide			
40–55 kg body weight	1,000 mg (18.2–25.0 mg/kg)	2,000 mg (36.4–50.0 mg/kg)	1,500 mg (27.3–37.5 mg/kg)
56–75 kg body weight	1,500 mg (20.0–26.8 mg/kg)	3,000 mg (40.0–53.6 mg/kg)	2,500 mg (33.3–44.6 mg/kg)
>75 kg body weight	2,000 mg (22.2–26.3 mg/kg)	4,000 mg (44.4–52.6 mg/kg)	3,000 mg (33.3–44.6 mg/kg)
Ethambutol			
40-55 kg body weight	800 mg (14.5–20.0 mg/kg)	2,000 mg (36.4–50.0 mg/kg)	1,200 mg/kg (21.8–30.0 mg/kg)
56-75 kg body weight	1,200 mg (16.0–21.0 mg/kg)	2,800 mg (37.3–50.0 mg/kg)	2,000 mg/kg (26.7–35.7 mg/kg)
>75 kg body weight	1,600 mg (17.8–21.0 mg/kg)	4,000 mg (44.4–52.6 mg/kg)	2,400 mg/kg (26.7–31.6 mg/kg)

* Some experts recommend that for severe tuberculosis infection (e.g., CNS, pericardial disease) considerations should be given to the use of adjuvant corticosteroids. The dosing and taper schedule should be individualized according to severity of disease and adjusted, as needed, in response to treatment.
† Acquired rifamycin resistance has been reported in patients with inadequate rifabutin levels while on 150 mg twice weekly dosing together with ritonavir-boosted PIs. May consider therapeutic drug monitoring when rifabutin is used with a ritonavir-boosted PI and adjust dose accordingly.
§ Non-nucleoside reverse transcriptase inhibitor.

TABLE 4. Criteria for discontinuing and restarting opportunistic infection prophylaxis for adults and adolescents with human immunodeficiency virus infection

Opportunistic infection	Criteria for discontinuing primary prophylaxis	Criteria for restarting primary prophylaxis	Criteria for discontinuing secondary prophylaxis/chronic maintenance therapy	Criteria for restarting secondary prophylaxis/ chronic maintenance
Pneumocystis pneumonia (PCP)	CD4+ count >200 cells/μL for >3 months in response to antiretroviral therapy (ART) **(AI)**	CD4+ count <200 cells/μL **(AIII)**	CD4+ count increased from <200 cells/μL to >200 cells/μL for ≥3 months in response to ART **(BII)** If PCP is diagnosed when CD4+ count >200 cells/μL, prophylaxis should probably be continued for life regardless of CD4+ count rise in response to ART **(CIII)**	CD4+ count <200 cells/μL **(AIII)**, or if PCP recurred at a CD4+ count >200 cells/ μL **(CIII)**
Toxoplasma gondii encephalitis (TE)	CD4+ count >200 cells/μL for >3 months in response to ART **(AI)**	CD4+ count <100–200 cells/μL **(AIII)**	Successfully completed initial therapy, remain asymptomatic of signs and symptoms of TE, and CD4+ count >200 cells/μL for >6 months in response to ART **(BI)**	CD4+ count <200 cells/μL **(AIII)**
Microsporidiosis	Not applicable	Not applicable	No signs and symptoms of non-ocular microsporidiosis and CD4+ count >200 cells/μL for >6 months in response to ART **(BIII)** Patients with ocular microsporidiosis should be on therapy indefinitely regardless of CD4+ count **(BIII)**	No recommendation
Disseminated *Mycobacterium avium* complex (MAC) disease	CD4+ count >100 cells/μL for ≥3 months in response to ART **(AI)**	CD4+ count <50 cells/μL **(AIII)**	If fulfill the following criteria **(BII)** • Completed ≥12 months therapy, and • No signs & symptoms of MAC, and • Have sustained (≥6 months) CD4+ count >100 cells/μL in response to ART	CD4+ count <100 cells/μL **(AIII)**
Bartonellosis	Not applicable	Not applicable	If fulfill the following criteria **(CIII)**: • Received 3–4 months of treatment • CD4+ count >200 cells/μL for ≥6 months • Certain specialists would only discontinue therapy if *Bartonella* titers have also decreased by fourfold	No recommendation
Mucosal candidiasis	Not applicable	Not applicable	If used, reasonable to discontinue when CD4+ count >200 cells/μL **(CIII)**	No recommendation
Cryptococcal meningitis	Not applicable	Not applicable	If fulfill the following criteria **(BII)** • Completed course of initial therapy • Remain asymptomatic of cryptococcosis • CD4+ count ≥200 cells/μL for >6 months in response to ART Certain specialists would perform a lumbar puncture to determine if cerebrospinal fluid is culture- and antigen-negative before stopping therapy **(CIII)**	CD4+ count <200 cells/μL **(AIII)**
Histoplasma capsulatum infection	If used, CD4+ count >150 cells/ μL for 6 months on ART **(BIII)**	For patients at high risk for acquiring histoplasmosis, restart at CD4+ count ≤150 cells/μL **(CIII)**	If fulfill the following criteria **(AI)** • Received itraconazole for ≥1 year • Negative blood cultures • CD4+ count >150 cells/μL for ≥6 months in response to ART • Serum *Histoplasma* antigen <2 units	CD4+ count ≤150 cells/μL **(BIII)**

TABLE 4. (*Continued*) Criteria for discontinuing and restarting opportunistic infection prophylaxis for adults and adolescents with human immunodeficiency virus infection

Opportunistic infection	Criteria for discontinuing primary prophylaxis	Criteria for restarting primary prophylaxis	Criteria for discontinuing secondary prophylaxis/chronic maintenance therapy	Criteria for restarting secondary prophylaxis/ chronic maintenance
Coccidioidomycosis	If used, CD4+ count ≥250 cells/ μL for ≥6 months **(CIII)**	If used, restart at CD4+ count <250 cells/μL **(BIII)**	**Only for patients with focal coccidioidal pneumonia (CIII)**: • Clinically responded to ≥12 months of antifungal therapy • CD4+ count >250 cells/μL • Receiving ART Suppressive therapy should be continued indefinitely, even with increase in CD4+ count on ART for patients with diffuse pulmonary **(AIII)**, disseminated **(AIII)**, or meningeal diseases **(AII)**	No recommendation
Cytomegalovirus retinitis	Not applicable	Not applicable	• CD4+ count >100 cells/μL for >3–6 months in response to ART **(BII)**. Therapy should be discontinued only after consultation with an ophthalmologist, taking into account magnitude and duration of CD4+ count increase, anatomic location of the lesions, vision in the contralateral eye, and the feasibility of regular ophthalmologic monitoring **(BII)**. • Routine (every 3 months) ophthalmologic follow-up is recommended for early detection of relapse or immune restoration uveitis **(AII)**	CD4+ count <100 cells/μL **(AIII)**
Penicillium marneffei infection	Not applicable	Not applicable	CD4+ count >100 cells/μL for ≥6 months in response to ART **(BII)**	CD4+ count <100 cells/μL **(AIII)** or if penicilliosis recurs at CD4+ count >100 cells/ μL **(CIII)**
Visceral leishmaniasis	Not applicable	Not applicable	Sustained (>3–6 months) increase in CD4+ count to >350 cells/μL in response to ART **(CIII)**	No recommendation
Isospora belli infection	Not applicable	Not applicable	Sustained increase in CD4+ count to >200 cells/μL for >6 months in response to ART and without evidence of *I. belli* infection **(BIII)**	No recommendation

TABLE 5. Common toxicities of agents for treatment and prevention of opportunistic infections

Drug class	Drugs	Toxicities
Anti-fungal agents	Amphotericin B deoxycholate and lipid formulations	Nephrotoxicity, infusion-related reactions (fever, chills, rigors, back pain, rarely, hypotension), electrolyte imbalances, anemia, thrombophlebitis, nausea, vomiting, hypertension. Lipid formulations might have lower incidence of nephrotoxicity and infusion-related reactions.
	Anidulafungin	Hepatotoxicity, histamine-related infusion reactions (flushing, rash, pruritus, hypotension, dyspnea; rare if infusion rate <1.1 mg/min), hypokalemia, diarrhea, deep vein thrombosis (rare)
	Caspofungin	Headache, thrombophlebitis, facial flushing, erythema, rash, infusion-related reactions (flushing, rash, pruritus, hypotension, dyspnea), hypokalemia, fever, hepatotoxicity
	Clotrimazole (troche)	Nausea, vomiting, diarrhea, anorexia, metallic taste, increase in serum transaminases
	Flucytosine	Bone marrow suppression, diarrhea, nausea, vomiting
	Fluconazole	Hepatotoxicity, rash
	Itraconazole	Hepatotoxicity, congestive heart failure, edema, hypokalemia, nausea, vomiting, diarrhea, abdominal pain, rash
	Micafungin	Hypersensitivity reaction (anaphylaxis and anaphylactoid reactions, rash, pruritus, facial flushing), hepatotoxicity, hemolysis, leukopenia, thrombophlebitis, nausea, vomiting, diarrhea, hypokalemia
	Nystatin (oral preparations)	Nausea, vomiting, anorexia, diarrhea, hypersensitivity reaction (rare)
	Posaconazole	Nausea, vomiting, diarrhea, abdominal pain, hepatotoxicity, edema, hypokalemia, QTc prolongation, rash
	Voriconazole	Visual disturbances, photosensitivity, rash, hepatotoxicity, peripheral edema, headache, delirium, hallucination, QTc prolongation, arrhythmias, hypotension
Anti-*Pneumocystis* pneumonia (PCP) agents	Atovaquone	Diarrhea, rash, nausea, vomiting, headache, hyponatremia, hyperglycemia, fever
	Clindamycin	Diarrhea, pseudomembranous colitis, rash
	Dapsone	Methemoglobinemia, hemolytic anemia (especially in patients with G-6-PD deficiency), neutropenia, rash, fever, hepatitis, hyperkalemia, peripheral neuropathy, hepatotoxicity
	Pentamidine	IV infusion: Nephrotoxicity, infusion-related hypotension, arrhythmias, pancreatitis, hypoglycemia, diabetes mellitus, hepatitis, electrolyte abnormalities Aerosolized therapy: Brochospasm, cough, dyspnea, tachypnea, metallic taste, pneumothorax (rare)
	Primaquine	Methemoglobinemia, hemolytic anemia (especially in patients with G-6-PD deficiency), abdominal cramps, nausea, vomiting
	Trimethoprim-sulfamethoxazole (TMP-SMX)	Rash, Stevens-Johnson Syndrome, bone marrow suppression, hepatotoxicity, increase in serum creatinine, nausea, vomiting, crystalluria, hyperkalemia
Antitoxoplasmosis agents (for atovaquone, clindamycin, and TMP-SMX, see Agents for PCP, above)	Pyrimethamine	Neutropenia, thrombocytopenia, megaloblastic anemia, rash
	Sulfadiazine	Rash, Stevens-Johnson Syndrome, bone marrow suppression, crystalluria, renal insufficiency, nausea, vomiting

TABLE 5. (*Continued*) Common toxicities of agents for treatment and prevention of opportunistic infections

Drug class	Drugs	Toxicities
Antimycobacterial agents	Amikacin	Nephrotoxicity, ototoxicity (both hearing loss and vestibular toxicity are possible)
	Azithromycin	Hepatotoxicity, ototoxicity (with prolonged use), rash, urticaria, pruritus, nausea, vomiting, abdominal pain, diarrhea
	Capreomycin	Nephrotoxicity, ototoxicity (both hearing loss and vestibular toxicity are possible). Intramuscular injections: injection-site reactions, pain
	Ciprofloxacin/ levofloxacin/ ofloxacin/ moxifloxacin	Nausea, vomiting, abdominal pain, diarrhea, headache, dizziness, sleep disturbances, tendonitis, photosensitivity, hypoglycemia, neurotoxicity (especially with high dose or in patients with renal dysfunction)
	Clarithromycin	Hepatotoxicity, ototoxicity (with high doses), headache, nausea, vomiting, abdominal cramps, diarrhea, rash
	Cycloserine	Neuropsychiatric toxicities (headache, somnolence, vertigo, tremor, dysarthria, irritability, confusion, paranoia, psychosis)
	Ethambutol	Optic neuritis, peripheral neuropathy, headache, nausea, vomiting, anorexia, hepatotoxicity, hyperuricemia, rash
	Ethionamide	Gastrointestinal side effects (dose related): nausea, vomiting, abdominal pain, metallic taste, anorexia; dizziness; drowsiness; depression; hepatotoxicity
	Isoniazid	Hepatotoxicity, peripheral neuropathy, optic neuritis
	Pyrazinamide	Hepatotoxicity, hyperuricemia, arthralgia, nausea, vomiting
	Rifabutin	Hepatotoxicity, uveitis, neutropenia, red-orange discoloration of body fluids, rash, arthralgia, anemia, thrombocytopenia
	Rifampin	Hepatotoxicity, red-orange discoloration of body fluids, thrombocytopenia, hemolytic anemia, rash, flu-like syndrome
	Streptomycin	Nephrotoxicity, ototoxicity (both hearing loss and vestibular toxicity are possible) Intramuscular injections: injection-site reactions, pain

TABLE 5. (*Continued*) Common toxicities of agents for treatment and prevention of opportunistic infections

Drug class	Drugs	Toxicities
Antiviral agents	Acyclovir	Crystalluria (with high dose or renal impairment), nausea, vomiting, neurotoxicity (high doses, especially in patients with renal impairment; agitation, confusion, hallucination, seizure, coma), nephrotoxicity (particularly after rapid IV infusion), thrombophlebitis at peripheral intravenous infusion site
	Adefovir	Nephrotoxicity, nausea, vomiting, asthenia
	Cidofovir	Nephrotoxicity, proteinuria, ocular hypotony, anterior uveitis/iritis, neutropenia, metabolic acidosis, asthenia. Side effects most likely related to co-administration of probenecid: rash, nausea, vomiting, anorexia
	Emtricitabine	Headache, nausea, hyperpigmentation, diarrhea, rash
	Entecavir	Headache, fatigue, dizziness, nausea
	Famciclovir	Headache, nausea, vomiting, anorexia
	Foscarnet	Nephrotoxicity, electrolyte imbalances (hypocalcemia, hypomagnesemia, hypophosphatemia, hyperphosphatemia, hypokalemia), penile ulceration, nausea, vomiting, anorexia, headache, seizure, thrombophlebitis
	Ganciclovir	Neutropenia, thrombocytopenia, anemia, IV-site-associated thrombophlebitis, confusion.
	Interferon-alfa and peginterferon-alfa	Influenza-like syndrome (fever, headache, fatigue, and myalgia), neuropsychiatric disorders (depression and suicidal ideation), neutropenia, thrombocytopenia, thyroid dysfunction, injection-site reactions, alopecia, nausea, anorexia, diarrhea, weight loss, development or exacerbation of autoimmune disorders, ophthalmologic disorders (retinal hemorrhage, retinal artery or vein obstructions, and cotton wool spots)
	Lamivudine	Nausea, vomiting
	Ribavirin	Hemolytic anemia, hyperbilirubinemia, nausea, vomiting, anorexia, dyspepsia, rash
	Telbuvidine	Nausea, vomiting, abdominal pain, increase in creatine kinase, headache, dizziness
	Tenofovir	Nausea, asthenia, renal insufficiency, hypophosphatemia, decrease in bone mineral density
	Valacyclovir	Nausea, vomiting, headache crystalluria (with high dose or renal impairment), neurotoxicity (high doses, especially in patients with renal impairment; agitation, confusion, hallucination, seizure, coma); at a high dose of 8 g/day: thrombotic thrombocytopenic purpura/hemolytic uremic syndrome reported in advanced human immunodeficiency virus patients and in transplant recipients
	Valganciclovir	Neutropenia, thrombocytopenia, anemia, nausea, confusion

TABLE 5. (*Continued*) Common toxicities of agents for treatment and prevention of opportunistic infections

Drug class	Drugs	Toxicities
Antiparasitic agents	Albendazole	Nausea, vomiting, hepatotoxicity, hypersensitivity reaction, neutropenia, dizziness, headache, reversible alopecia
	Atovaquone-proguanil	Pruiritis, abdominal pain, vomiting, diarrhea, anorexia, erythema multiformae, asthenia, dizziness, headache, oral ulcers
	Benznidazole	Peripheral neuropathy, bone marrow suppression, rash
	Chloroquine & hydroxychloroquine	Headache, pruritus, skin pigmentation, nausea, vomiting, anorexia, photosensitivity, visual disturbances, QTc prolongation, neuromyopathy (rarely with long-term use)
	Fumagillin (investigational)	Oral therapy: neutropenia, thrombocytopenia, vertigo, nausea, vomiting, diarrhea, anorexia, abdominal cramps Ocular therapy: minimal systemic effect or local effect
	Mefloquine	Depression, psychosis, rash, vomiting, epigastric pain, nausea, agitation, dizziness, headache, insomnia, abnormal dreams, arrhythmias
	Miltefosine	Nausea, vomiting, leukocytosis, thrombocytosis, nephrotoxicity, retinal degeneration, diarrhea
	Nifurtimox	Rash, nausea, vomiting, anorexia, neuropsychiatric symptoms, hepatotoxiicty, arthralgia, myalgia,
	Nitazoxanide	Nausea, vomiting, diarrhea, abdominal pain, hypotension, headache
	Pentavalent antimony (sodium stibogluconate)	Nausea, vomiting, abdominal pain, anorexia, pancreatitis, hepatotoxicity, arthralgia, myalgia, ECG changes (with higher than 20 mg/kg dose), rash, thrombophlebitis, leukopenia, anemia, thrombocytopenia
	Quinidine glucuronate	QTc prolongation, lightheadedness, diarrhea, cramping, palpitation headache, rash
	Quinine	Headache, nausea, vomiting, diarrhea, tinnitus, blurred vision, cinchonism, hypersensitivity reaction
	Tetracycline	Photosensitivity, tooth discoloration if taken by infants and children, pruritus, nausea, vomiting, diarrhea, hepatotoxicity, rash
Treatment for syphilis (for azithromycin, see Antimycobacterial agents, above)	Ceftriaxone	Cholelithiasis, rash Intramuscular injections: injection-site reactions, pain
	Doxycycline	Photosensitivity reaction, nausea, vomiting, diarrhea, esophageal ulceration, thrombophlebitis (with IV infusion)
	Penicillin G	All penicillin G preparations: Hypersensitivity reactions (immediate or delayed reaction), bone marrow suppression (rare), drug fever Benzathine penicillin G: Injection-site reactions (pain and erythema) Procaine penicillin G: Injection-site reactions (pain and erythema) Aqueous crystalline penicillin G: Thrombophlebitis, neurotoxicity at high doses (especially in patients with renal dysfunction)
Other antibacterial agents	Erythromycin	Nausea, vomiting, abdominal pain, hepatotoxicity, cholestatic jaundice, ototoxicity (hearing loss, tinnitus), rash, cardiac arrhythmia

TABLE 6. Substantial pharmacokinetic drug-drug interactions for drugs used in the treatment of opportunistic infections

Drugs	Interacting with	Mechanism/effects	Recommendations
Acyclovir	Probenecid (with cidofovir)	Probenecid might decrease renal clearance of acyclovir by 32%, increasing acyclovir area under the concentration curve (AUC)	No dosage adjustment; monitor for acyclovir toxicities
Atovaquone	Rifabutin	Atovaquone concentration (conc.) decreased 34%; Rifabutin conc. decreased 19%	This combination should be avoided
	Rifampin	Atovaquone conc. decreased 52%; Rifampin conc. increased 37%	This combination should be avoided
	Tetracycline	Atovaquone conc. decreased 40%	This combination should be avoided; interaction study with doxycycline not available
	Zidovudine	Zidovudine AUC increased 31%, possibly because of atovaquone inhibition of zidovudine glucuronidation	No dosage adjustment recommended, monitor for zidovudine toxicities
Caspofungin	Efavirenz, nevirapine, nelfinavir	Possible decreases in caspofungin conc. based on regression analyses of patient pharmacokinetic data; no formal pharmacokinetic study available	Manufacturer recommends considering increasing maintenance dose of caspofungin to 70 mg/day when co-administered with the interacting drugs
	Rifampin	Caspofungin conc. decreased 30%	Caspofungin dose should be increased to 70 mg/day
Cidofovir (plus probenecid)	Acyclovir, cephalosporins, dapsone, fluoroquinolones, ganciclovir, penicillins, valacyclovir, valganciclovir, zidovudine	Probenecid might decrease renal clearance of these drugs, increasing plasma conc.	Because of the infrequent dosing of probenecid when used with cidofovir, no dosage adjustment is necessary for interacting drugs; monitor for dose-related toxicities
Ciprofloxacin	Didanosine buffered formulations	Decreased ciprofloxacin absorption attributed to chelation with magnesium-aluminum buffer	Administer didanosine buffered preparation at least 2 hours after or 6 hours before ciprofloxacin
	Cidofovir (plus probenecid)	Probenecid might reduce renal clearance of ciprofloxacin, increasing plasma conc.	No dosage adjustment necessary; monitor for ciprofloxacin toxicities

TABLE 6. (*Continued*) Substantial pharmacokinetic drug-drug interactions for drugs used in the treatment of opportunistic infections

Drugs	Interacting with	Mechanism/effects	Recommendations
Clarithromycin (CYP3A4 inhibitor and substrate)	Atazanavir	Atazanavir minimum conc. (Cmin) increased 91%; Clarithromycin AUC increased 94%; Cmin increased 160%	Because of concerns about QTc prolongation, decrease clarithromycin dose 50% or switch to azithromycin
	Delavirdine	Delavirdine AUC increased 44%; clarithromycin AUC increased 100% and 14-OH clarithromycin AUC decreased 75%	No dosage adjustment recommended; might consider clarithromycin dose adjustment in patients with renal insufficiency; monitor for clarithromycin toxicities; or switch to azithromycin
	Darunavir	Clarithomycin AUC increased 57%; Cmin increased 174%	No dosage change in patients with normal renal function. *CrCl (mL/min)* — *Clarithromycin* 30-60 — decrease dose by 50% <30 — decrease dose by 75%
	Efavirenz	Clarithromycin AUC decreased 39%; 14-OH clarithromycin AUC increased 34%	Significance unknown, no dosage adjustment recommended; some recommend switching to azithromycin
	Etravirine	Clarithromycin AUC decreased 39%, 14-OH clarithromycin AUC increased by 21%; etravirine Cmin increased by 46%; AUC increased 42%	Alternative to clarithromycin should be considered
	Itraconazole	Possible bi-directional CYP3A4 inhibition and increased AUC of both drugs	Monitor for toxicities of both itraconazole and clarithromycin or switch to azithromycin
	Lopinavir/ritonavir	Increased clarithromycin AUC and decrease in 14-OH clarithromycin AUC	No dosage change in patients with normal renal function. *CrCl (mL/min)* — *Clarithromycin* 30-60 — decrease dose by 50% <30 — decrease dose by 75%
	Maraviroc	Potential for inhibition of maraviroc metabolism	Maraviroc: Reduce dose to 150 mg bid or switch clarithromycin to azithromycin

TABLE 6. (*Continued*) Substantial pharmacokinetic drug-drug interactions for drugs used in the treatment of opportunistic infections

Drugs	Interacting with	Mechanism/effects	Recommendations
Clarithromycin (CYP3A4 inhibitor and substrate) (*Continued*)	Rifabutin	Clarithromycin AUC decreased by 44%; rifabutin AUC increased 76%–99%	Might need clarithromycin dose increase and decrease rifabutin dose; might result in increased rifabutin toxicities; some recommend switching to azithromycin
	Rifampin	Decreased mean clarithromycin conc. by 87%	This combination should be avoided; consider switching to azithromycin
	Ritonavir	Clarithromycin AUC increased 77% and decrease in 14-OH clarithromycin AUC	No dosage change in patients with normal renal function. *CrCl (mL/min)* — *Clarithromycin* 30–60 — decrease dose 50% < 30 — decrease dose 75%
	Tipranavir	Clarithromycin AUC: increased 19%; Cmin: increased 68% 14-hydroxyclarithromycin AUC: decreased 97%; Cmin: decreased 95% Tipranavir AUC: increased 66%; Cmax: increased 40%; Cmin: increased 100%	Monitor for tipranavir toxicity and possible decreased clarithromycin effects
Dapsone	Rifampin	Decreased dapsone level 7–10-fold and dapsone half-life ($t_{1/2}$) decreased from 24 to 11 hours	Reduced dapsone activities; might consider increasing dapsone dose or use alternative agent
Doxycycline	Atovaquone	Tetracycline decreased atovaquone conc. 40%; effect of doxycycline on atovaquone unknown	Until doxycycline-atovaquone interaction data become available, avoid this combination if possible
	Didanosine buffered formulations	Decreased doxycycline absorption attributed to chelation with magnesium-aluminum buffer	Separate doxycycline with didanosine by at least 2 hours or use didanosine enteric-coated capsule
	Rifampin	Increased doxycycline clearance, decreased $t_{1/2}$ and AUC	Potential for decreased doxycycline efficacy, monitor closely for therapeutic failure
Erythromycin (CYP3A4 inhibitor)	Itraconazole	Potential for bi-directional inhibition of hepatic metabolism and increased serum conc. of both	Monitor for toxicities of both drugs
Fluconazole (CYP3A4 inhibitor)	Nevirapine	Nevirapine conc. increased by 100% compared with historic control	Recommended monitor for nevirapine toxicity
	Rifabutin	Rifabutin AUC increased 80%; no effect on fluconazole levels	Monitor for rifabutin toxicity or might consider dose reduction to 150 mg/day
	Rifampin	Fluconazole AUC decreased by 23%–56%; no change in rifampin conc.	Monitor for antifungal efficacy, might need to increase fluconazole dose
	Saquinavir	Saquinavir AUC increased 50%	Clinical significance unknown
	Tipranavir	Tipranavir AUC increased 50%; Cmin increased 69%	Monitor for tipranavir toxicity; fluconazole doses >200 mg/day not recommended
	Zidovudine	Fluconazole decreased glucuronidation of zidovudine; fluconazole 400 mg/day results in increased zidovudine AUC by 74%	Monitor for zidovudine toxicities

TABLE 6. (*Continued*) Substantial pharmacokinetic drug-drug interactions for drugs used in the treatment of opportunistic infections

Drugs	Interacting with	Mechanism/effects	Recommendations
Ganciclovir	Didanosine buffered formulations (study with enteric coated didanosine has not been done)	Didanosine AUC increased 78% with IV ganciclovir and increased 111% with oral ganciclovir	Might consider reducing didanosine dose; monitor for didanosine toxicities
	Cidofovir (plus probenecid)	Probenecid might decrease ganciclovir clearance and increase ganciclovir conc.	Because of the infrequent dosing of probenecid when used with cidofovir, no dosage adjustment is necessary; monitor for dose-related toxicities
Itraconazole (CYP3A4 inhibitor and substrate)	Clarithromycin	Potential for bi-directional inhibition of CYP3A4 metabolism with increased AUC of itraconazole and/or interacting drug(s)	Monitor for toxicities of clarithromycin; monitor itraconazole level and toxicities; or switch to azithromycin
	Delavirdine	Potential for bi-directional inhibition of CYP3A4 metabolism with increased AUC of itraconazole and/or delavirdine	Monitor for toxicities of delavirdine; monitor itraconazole level and toxicities
	Didanosine buffered preparation	Might decrease itraconazole oral absorption because of increased gastric pH from antacid in the didanosine preparation	Administer itraconazole at least 2–4 hours before didanosine buffered tablets, use didanosine enteric coated capsule, or take itraconazole with cola beverage to decrease gastric pH
	Efavirenz	Decreased itraconazole conc.	Monitor itraconazole level and adjust dose accordingly
	Erythromycin	Potential for bi-directional inhibition of CYP3A4 metabolism with increased AUC of itraconazole and/or erythromycin	Monitor for toxicities of erythromycin; monitor itraconazole level and toxicities
	Etravirine	Etravirine concentration may be increased, itraconazole concentration may be decreased. Extent of the interaction unknown.	Dose adjustment with itraconazole might be necessary – depending on the presence of other concomitant antiretrovirals (e.g., protease inhibitors). Monitor itraconazole level and dose adjust accordingly
	Maraviroc	Potential for inhibition of maraviroc metabolism	Maraviroc: Reduce dose to 150 mg bid
	Nevirapine	Potential for induction of itraconazole metabolism and decrease in itraconazole conc.	Monitor itraconazole level and adjust accordingly; monitor therapeutic efficacy
	Protease inhibitors other than ritonavir	Potential for bi-directional inhibition of CYP3A4 metabolism with increased AUC of itraconazole and/or PIs	Monitor for toxicities of protease inhibitors; monitor itraconazole level and toxicities (especially in patients with ritonavir-boosted PI regimens)
	Rifabutin	Decrease in itraconazole conc. by 70%; potential for inhibition of rifabutin metabolism and increased rifabutin conc.	Avoid concomitant use if possible; if the combination is to be used, monitor itraconazole level and adjust dose accordingly; monitor for rifabutin toxicity, consider monitoring rifabutin conc.
	Rifampin	Itraconazole AUC decreased 64%–88%; no change in rifampin conc.	Avoid concomitant use if possible. If the combination is to be used, monitor itraconazole level and adjust dose accordingly; monitor therapeutic response
	Ritonavir	Potential for substantial increase in itraconazole conc.	Might require reduced itraconazole dose; monitor itraconazole level and toxicities

TABLE 6. (*Continued*) Substantial pharmacokinetic drug-drug interactions for drugs used in the treatment of opportunistic infections

Drugs	Interacting with	Mechanism/effects	Recommendations
Ketoconazole (CYP3A4 substrate)	Darunavir	Darunavir AUC increased 42%; Cmin increased 73%; ketoconazole AUC increased 212%; Cmin increased 868%	Combination not recommended
	Delavirdine	Delavirdine Cmin increased 50%	Monitor for delavirdine toxicities
	Didanosine buffered formulations	Might decrease oral absorption of ketoconazole because of increased gastric pH from antacid in the didanosine preparation	Space doses of ketoconazole and didanosine by at least 2 hours or administer ketoconazole with cola beverage to decrease pH
	Etravirine	Etravirine concentration may be increased, ketonconazole concentration may be decreased. Extent of interaction unknown.	Magnitude of the interaction also depends on concomitant drugs used. Use with caution or use alternative agents.
	Fosamprenavir	Amprenavir AUC increased 31%; ketoconazole AUC increased 44%	Monitor for toxicities of each drug
	Indinavir	Indinavir AUC increased 68%; no substantial change in ketoconazole conc.	Decrease indinavir dose to 600 mg every 8 hours
	Lopinavir/ritonavir	Ketoconazole AUC increased threefold; no substantial change in lopinavir pharmacokinetics	Decrease ketoconazole dose and monitor for toxicities
	Maraviroc	Maraviroc AUC increased 400%	Reduce maraviroc dosage to 150 mg twice daily
	Nevirapine	Ketoconazole AUC decreased 63%; nevirapine AUC increased 15%–30%	Consider alternative antifungal or monitor for ketoconazole efficacy
	Rifabutin	Possible increase in rifabutin conc. and decrease in ketoconazole conc.	Monitor for rifabutin toxicities and ketoconazole efficacy
	Rifampin	Ketoconazole levels decreased 50%	Avoid concomitant use if possible; consider alternative antifungal and/or antimycobacterial agent(s)
	Ritonavir	Ketoconazole AUC increased 3.4-fold	Ketoconazole dose >200 mg/day not recommended; monitor for ketoconazole toxicities
	Tipranavir/ritonavir	Possible increase in ketoconazole conc.	Use with caution; ketoconazole doses >200 mg/day not recommended
Mefloquine	Ritonavir	Ritonavir AUC decreased 31%, and Cmin: decreased 43%; No substantial change in mefloquine pharmacokinetics	Avoid combination if possible. If used, monitor for signs of antiretroviral failure.
Posaconazole	Etravirine	Etravirine concentration may be increased, posaconazole concentration unchanged	No dosage adjustment necessary
	Rifabutin	Posaconazole AUC decreased 49%; rifabutin AUC increased 72%	Avoid concomitant use if possible, or monitor drug concentrations and adjust doses accordingly
	Rifampin	Posaconazole level may be reduced significantly	Avoid combination if possible, if used, monitor posaconazole level and adjust dose if necessary
Pyrazinamide	Zidovudine	Decreased pyrazinamide conc. in one study	Monitor therapeutic efficacy or consider monitoring pyrazinamide level

TABLE 6. (*Continued*) Substantial pharmacokinetic drug-drug interactions for drugs used in the treatment of opportunistic infections

Drugs	Interacting with	Mechanism/effects	Recommendations
Ribavirin	Didanosine	Increased intracellular levels of dideoxyadenosine triphosphate (ddA-TP)	This combination should be avoided; increased didanosine (ddI)-associated mitochondrial toxicities
	Zidovudine	Decreased intracellular activities of zidovudine against HIV in vitro	Potential for worsening of HIV suppression; monitoring HIV viral load
Rifabutin* (CYP3A4 inducer and substrate)	Atazanavir	Rifabutin AUC increased 210%; Cmin increased 343%; minimal change in atazanavir pharmacokinetics	Decrease rifabutin dose to 150 mg tiw, or adjust dose based on rifabutin level*
	Atovaquone	Atovaquone conc. decreased 34%; rifabutin conc. decreased 19%	This combination should be avoided
	Clarithromycin	Rifabutin AUC increased 76% because of inhibition of hepatic metabolism; clarithromycin AUC might be reduced	Consider reducing rifabutin dose, monitor for rifabutin toxicities, or switching macrolide to azithromycin
	Darunavir	Darunavir might inhibit metabolism of rifabutin	Decrease rifabutin dose to 150 mg tiw, or adjust dose based on rifabutin level*
	Delavirdine	Delavirdine AUC decreased 80%; rifabutin AUC increased 100%	This combination should be avoided
	Didanosine buffered formulation	Decreased rifabutin oral absorption	Space rifabutin and didanosine buffered formulation apart by at least 2 hours or use enteric coated didanosine capsule
	Efavirenz	Rifabutin AUC decreased 38%; no change in efavirenz conc.	Increase rifabutin dose to 450–600 mg/day or 600 mg two to three times weekly; effect of efavirenz + PI(s) on rifabutin conc. has not been studied
	Etravirine	Etravirine Cmin decreased by 35% and AUC decreased by 37%; rifabutin AUC decreased by 17%	Use standard rifabutin dose of 300 mg daily if it is not used with a ritonavir-boosted PI. In patients receiving ritonavir-boosted darunavir or saquinavir, if rifabutin is needed, consider alternative antiretroviral to etravirine.
	Fluconazole	Rifabutin AUC increased 80% because of inhibition of hepatic metabolism	Consider reducing rifabutin dose to 150 mg daily and monitor rifabutin level or monitor for rifabutin toxicities

* Acquired rifamycin resistance has been reported when ritonavir-boosted PIs are used with rifabutin 150 mg twice weekly. Consider therapeutic drug monitoring and adjust rifabutin dose based on levels

TABLE 6. (*Continued*) Substantial pharmacokinetic drug-drug interactions for drugs used in the treatment of opportunistic infections

Drugs	Interacting with	Mechanism/effects	Recommendations
Rifabutin* (CYP3A4 inducer and substrate) (*Continued*)	Fosamprenavir	Rifabutin AUC increased 193%; no change in amprenavir conc.	Decrease rifabutin dose to 150 mg tiw, or adjust dose based on rifabutin level*
	Itraconazole	Itraconazole conc. decreased by 70%; potential for inhibition of rifabutin metabolism and increased rifabutin conc.	Avoid concomitant use if possible; if the combination is to be used, monitor itraconazole and rifabutin level and adjust dose accordingly; monitor for rifabutin toxicity
	Indinavir	Rifabutin AUC increased 204%; indinavir AUC decreased 32%	Decrease rifabutin dose to 150 mg tiw, or adjust dose based on rifabutin level and increase unboosted indinavir dose to 1,000 mg every 8 hours*
	Ketoconazole	Possible increase in rifabutin conc. and decrease in ketoconazole conc.	Monitor for rifabutin toxicities and ketoconazole efficacy
	Lopinavir/ritonavir	Rifabutin AUC increased 303%; 25-O-des-acetyl rifabutin AUC increased 47.5-fold	Decrease rifabutin dose to 150 mg tiw, or adjust dose based on rifabutin level*
	Nelfinavir	Rifabutin AUC increased 207%; insignificant change in nelfinavir conc.	Decrease rifabutin dose to 150 mg tiw, or adjust dose based on rifabutin level*
	Posaconazole	Posaconazole AUC decreases 49%; Rifabutin AUC increases 72%	Avoid concomitant use if possible; otherwise, monitor posaconazole and rifabutin level and adjust dose and monitor clinical responses of each
	Ritonavir	Rifabutin AUC increased 430%; no change in ritonavir conc.	Decrease rifabutin dose to 150 mg tiw, or adjust dose based on rifabutin level*
	Saquinavir	Saquinavir AUC decreased 43%; no change in rifabutin conc.	Saquinavir should not be used without ritonavir-boosting. Decrease rifabutin dose to 150 mg tiw, or adjust dose based on rifabutin level*
	Tipranavir/ritonavir	Rifabutin AUC: increased 190%; Cmin: increased 114%; 25-O-desacetyl-rifabutin AUC: increased 1971%; Cmin: increased 683%	Decrease rifabutin dose to 150 mg tiw, or adjust dose based on rifabutin level*
	Voriconazole	Voriconazole AUC decreased 79%; rifabutin AUC increased threefold	This combination should be avoided; if used in combination, monitor voriconazole and rifabutin levels, clinical responses, and toxicities

* Acquired rifamycin resistance has been reported when ritonavir-boosted PIs are used with rifabutin 150 mg twice weekly. Consider therapeutic drug monitoring and adjust rifabutin dose based on levels

TABLE 6. (*Continued*) Substantial pharmacokinetic drug-drug interactions for drugs used in the treatment of opportunistic infections

Drugs	Interacting with	Mechanism/effects	Recommendations
Rifampin (Potent CYP3A4 & UGT1A1 inducer)	Atazanavir	Substantial decrease in atazanavir Cmin and AUC despite double dosing or boosting with ritonavir	This combination should be avoided
	Atovaquone	Atovaquone conc. decreased 52%; rifampin conc. increased 37%	This combination should be avoided
	Caspofungin	Caspofungin conc. decreased 30%	Caspofungin dose should be increased to 70 mg/day
	Clarithromycin	Decreased mean clarithromycin conc. 87%	This combination should be avoided; consider switching clarithromycin to azithromycin
	Dapsone	Dapsone half-life decreased from 24 to 11 hr; Reduced dapsone activity expected	Consider alternative to dapsone; rifabutin might be an alternative
	Darunavir	Potential substantial decrease in darunavir concentration	This combination should be avoided
	Delavirdine	Delavirdine AUC decreased 95%; no change in rifampin conc.	This combination should be avoided
	Efavirenz	Efavirenz AUC decreased 22%; no change in rifampin conc.	No dosage adjustment or consider increasing efavirenz dose to 800 mg/day or monitor efavirenz concentration
	Etravirine	Potential significant decrease in etravirine concentration	This combination should be avoided
	Fluconazole	Fluconazole AUC decreased by 23%–56%; no change in rifampin conc.	Might need to increase fluconazole dose
	Fosamprenavir	Amprenavir AUC decreased 82%, Cmin decreased 92%; no change in rifampin conc.	This combination should be avoided; effect of rifampin on ritonavir and amprenavir has not been studied

TABLE 6. (*Continued*) Substantial pharmacokinetic drug-drug interactions for drugs used in the treatment of opportunistic infections

Drugs	Interacting with	Mechanism/effects	Recommendations
Rifampin (Potent CYP3A4 & UGT1A1 inducer) (*Continued*)	Indinavir	Indinavir AUC decreased 89%; rifampin conc. slightly increased	This combination should be avoided
	Itraconazole	Itraconazole AUC decreased 64%–88%; no change in rifampin conc.	Avoid concomitant use if possible; if the combination is to be used, monitor itraconazole level and adjust dose accordingly; monitor clinical response
	Ketoconazole	Ketoconazole levels decreased 50%	Avoid concomitant use if possible; consider alternative antifungal and/or antimycobacterial agent(s)
	Lopinavir/ritonavir	Lopinavir AUC decreased 75% and Cmin decreased 99%; rifampin AUC might be increased	This combination should be avoided
	Maraviroc	Maraviroc AUC decreased 63%, Cmin decreased 67%	This combination should be avoided
	Nelfinavir	Nelfinavir AUC decreased 82%; no change in rifampin conc.	This combination should be avoided
	Nevirapine	Nevirapine maximum concentration (Cmax) and AUC decreased by >50%; no change in rifampin conc.	This combination should be used with caution; monitor antiretroviral response
	Posaconazole	Posaconazole level may be reduced substantially	Avoid combination if possible, if used, monitor posaconazole level and adjust dose if necessary
	Raltegravir	Rifampin induces raltegravir glucuronidation via UGT1A1 enzyme – reducing AUC by 40% & Cmin by 60%	Increase raltegravir dose to 800 mg PO bid
	Ritonavir 600 mg BID	Ritonavir AUC decreased 35%; no change in rifampin conc.	Monitor for antiretroviral activity of ritonavir
	Saquinavir	Saquinavir AUC decreased 84%; no change in rifampin conc.	This combination should be avoided due to pharmacokinetic interaction; rifampin use with ritonavir-boosed saquinavir is contraindicated because of high incidence of serious hepatotoxicity
	Tipranavir	Potentially substantial decrease in tipranavir concentration	This combination should be avoided
	Voriconazole	Voriconazole AUC decreased 96%	This combination should be avoided
	Zidovudine	Rifampin increased zidovudine glucuronidation, decreasing zidouvdine AUC 47%	Monitor for zidovudine efficacy

TABLE 6. (*Continued*) Substantial pharmacokinetic drug-drug interactions for drugs used in the treatment of opportunistic infections

Drugs	Interacting with	Mechanism/effects	Recommendations
Tenofovir	Acyclovir, cidofovir, ganciclovir, valacyclovir, valganciclovir	Potential for compete active tubular secretion of these drugs	Monitor for toxicities of these drugs and tenofovir
	Atazanavir	Atazanavir Cmin decreased 40%; mechanism unknown	Co-administer with ritonavir at a dose of ritonavir 100 mg daily plus atazanavir 300 mg daily
	Didanosine	Increased didanosine AUC by 44%–60%; no change in tenofovir AUC	Reduce didanosine dose (from 400 mg to 250 mg in patients weighing >60 mg); monitor for didanosine-associated toxicities; discontinue didanosine if serious toxicity occurs
	Lopinavir/ritonavir	Tenofovir AUC increased by 34%	Significance unknown, monitor for tenofovir toxicities
Valganciclovir	Cidofovir (plus probenecid)	Probenecid might decrease ganciclovir renal clearance and increase ganciclovir conc.	Because of the infrequent dosing of probenecid when used with cidofovir, no dosage adjustment is necessary; monitor for dose-related toxicities
	Didanosine buffered formulation	Oral ganciclovir increased didanosine AUC 111%	Monitor for didanosine toxicities; study with valganciclovir and didanosine enteric coated formuation has not been done
Voriconazole (CYP 2C9, 2C19, & 3A4 substrate and inhibitor)	Atazanavir	Voriconazole AUC: decreased 39%	Avoid combination if possible
	Delavirdine	Potential bi-directional inhibition of metabolism, increasing conc. of both	No formal interaction studies; monitor for toxicities
	Efavirenz	Voriconazole Cmax decreased 61%; AUC decreased 77%; efavirenz Cmax increased 98% and AUC increased 44%	Do not coadminister at standard doses; increase voriconazole to 400 mg Q12H and decrease efavirenz to 300 mg QHS
	Etravirine	Potential for increase of both etravirine and voriconazole concentration	Monitor for voriconazole toxicities. Consider therapeutic drug monitoring and adjust dose accordingly.
	Nevirapine	Potential induction of voriconazole metabolism, decreasing voriconazole conc.	No formal interaction studies; monitor for therapeutic failure of voriconazole; consider monitoring voriconazole level
	Protease inhibitors (except atazanavir and ritonavir)	Potential bi-directional inhibition of metabolism, increasing conc. of both drugs; indinavir and voriconazole lead to no substantial interaction	No formal interaction studies; monitor for toxicities, consider therapeutic drug monitoring
	Rifabutin	Voriconazole AUC decreased 79%; Rifabutin AUC increased 3-fold	This combination should be avoided
	Rifampin	Voriconazole AUC decreased 96%	This combination should be avoided
	Ritonavir	Ritonavir 400 mg q12h: Voriconazole AUC decreased 82% Ritonavir 100 mg q12h: Voriconazole AUC decreased by 39%	Avoid combination if possible, esp. ritonavir dose at 400 mg q12h. If use with ritonavir 100 mg q12h, consider monitoring voriconazole level and adjust dose accordingly.

.

TABLE 7. Antiretroviral anti-infective drug combinations that should be avoided*

First Drug	Second Drug	Reason
Ribavirin	Didanosine	Increased intracellular levels of ddA-TP, increase in ddI-associated mitochondrial toxicities (e.g., lactic acidosis, pancreatitis, and peripheral neuropathy)
Rifabutin	Atovaquone	Atovaquone concentration (conc.) decreased 34%; rifabutin conc. decreased 19%
	Delavirdine	Delavirdine area under the conc. curve (AUC) decreased 90%; rifabutin AUC increased 100%
	Etravirine (use with darunavir/ritonavir or saquinavir/ritonavir)	If rifabutin therapy is needed, consider alternative antiretroviral to etravirine – as rifabutin might reduce etravirine concentration.
	Itraconazole	Itraconazole conc. decreased 70%; potential for inhibition of rifabutin metabolism and increased rifabutin conc.
	Posaconazole	Posaconazole AUC decreased by 49%; rifabutin AUC increased by 72%
	Voriconazole	Voriconazole AUC decreased 79%; rifabutin AUC increased threefold
Rifampin	Atazanavir	Pharmacokinetic data not available; expect rifampin to decrease atazanavir concentrations substantially, as seen with other protease inhibitors
	Atovaquone	Atovaquone conc. decreased 52%; rifampin conc. increased 37%
	Clarithromycin	Mean clarithromycin conc. decreased 87%
	Darunavir	Pharmacokinetic study not available; expect rifampin to decrease darunavir concentration substantially, as seen with other protease inhibitors
	Delavirdine	Delavirdine AUC decreased 95%; no change in rifampin conc.
	Etravirine	Pharmacokinetic data not available; expect rifampin to decrease etravirine concentrations substantially
	Fosamprenavir	No study done with fosamprenavir; amprenavir AUC decreased 82%; Cmin decreased 92%
	Indinavir	Indinavir AUC decreased 89%; rifampin conc. slightly increased
	Itraconazole	Itraconazole AUC decreased 64%–88%; no change in rifampin conc.
	Ketoconazole	Ketoconazole levels decreased 50%; rifampin maximum concentration (Cmax) decreased 40%–50% probably because of impaired rifampin oral absorption
	Lopinavir/ritonavir	Lopinavir AUC decreased 75% and Cmin decreased 99%; rifampin AUC might be increased
	Maraviroc	Maraviroc AUC decreased 63%, Cmin decreased 67%
	Nelfinavir	Nelfinavir AUC decreased 82%; no change in rifampin conc.
	Posaconazole	Posaconazole concentration may be decreased substantially
	Saquinavir	Saquinavir AUC decreased 82%; no change in rifampin concentration
	Tipranavir	Pharmacokinetic study not available; expect rifampin to decrease tipranavir concentration substantially, as seen with other protease inhibitors
	Voriconazole	Voriconazole AUC decreased 96%
Voriconazole	Ritonavir 400 mg q12h	Voriconazole AUC decreased 82%

Note: In some cases, the benefit of concomitant use of these agents may outweigh the risks. If possible, monitor drug concentrations and adjust doses accordingly; also monitor clinical responses or toxicities.

TABLE 8. Dosage adjustment in renal insufficiency

Drugs	Normal dose	Dosage adjustment in renal insufficiency: Creatinine clearance (mL/min)	Dosage adjustment in renal insufficiency: Dose
Acyclovir	IV dose for serious HSV/VZV infections: 10 mg/kg body weight q8h PO dose for herpes zoster: 800 mg q4h (5x/day)	25–50 10–25 0–10 hemodialysis 10–25 0–10	10 mg/kg body weight q12h 10 mg/kg q24h 5 mg/kg q24h adminster additional dose post dialysis 800 mg q8h 800 mg q12h
Amikacin	IV 15 mg/kg/day or 25 mg/kg tiw		25 mg/kg tiw initially, adjust to achieve target peak concentration while allowing sufficient time for clearance. TDM is recommended.
Amphotericin B	0.5–1.0 mg/kg/day IV (amphotericin B deoxycholate); or 3–6 mg/kg/day IV (lipid formulation)		No dosage adjustment necessary; alternative antifungals might be considered if renal insufficiency occurs during therapy
Chloroquine	600 mg (2 tabs) STAT dose followed by 300 mg (1 tab) at 6, 24, and 48 hours for a total dose of 1500 mg	<10	50% of dose
Cidofovir	5 mg/kg IV two times each week, then every 2 weeks (with probenecid & hydration)	If serum creatinine increases 0.3–0.4 mg/dL >baseline; If serum creatinine increases ≥0.5 mg/dL >baseline or ≥3+ proteinuria	3 mg/kg per dose Discontinue therapy
Ciprofloxacin	500 mg PO bid	30–50 5–29 Patients on hemodialysis or peritoneal dialysis	250 mg q12hr 250 mg q18h (or 375 mg q24h) 250 mg q24hr (administered after dialysis)
Clarithromycin	500 mg PO bid	<30	250 mg bid or 500 mg daily
Emtricitabine	200 mg once daily	30–49 15–29 <15 or hemodialysis	200 mg q48h 200 mg q72h 200 mg q96h
Emtricitabine/tenofovir	200 mg/300 mg PO one tablet daily	30–49 <30 or hemodialysis	One tablet q48h Coformulated tablet should not be used. Use individual formulation and dose adjust according to recommendations.
Entecavir	Usual dose: 0.5 mg once daily; Lamivudine (3TC)-refractory HBV: 1 mg once daily	30–<50 10–<30 <10 or hemodialysis or CAPD	Usual: 0.25 mg daily; 0.15 mg daily; 0.05 mg daily 3TC-refractory: 0.5 mg daily; 0.3 mg daily; 0.1 mg daily
Ethambutol	15–20 mg/kg q24h PO	10–50 <10 hemodialysis	15–20 mg/kg q24-36h 15–20 mg/kg q48h 15–20 mg/kg tiw after hemodialysis TDM may be considered
Fluconazole	200–800 mg PO or IV daily	≥50 <50 hemodialysis	Full dose 50% of full dose Full dose after dialysis

TABLE 8. (*Continued*) Dosage adjustment in renal insufficiency

Drugs	Normal dose	Dosage adjustment in renal insufficiency	
		Creatinine clearance (mL/min)	Dose
Flucytosine	25 mg/kg PO q6h	20–40 10–20 hemodialysis	25 mg/kg q12h 25 mg/kg q24h 25–50 mg/kg q48–72h (after hemodialysis)
Foscarnet	120–180 mg/kg/day	Dosage adjustment according to calculated CrCl/kg; consult package labeling for dosing table	
Ganciclovir	Induction therapy: 5 mg/kg IV q12h	50–69 25–49 10–24 <10 or on hemodialysis	2.5 mg/kg q12h 2.5 mg/kg q24h 1.25 mg/kg q24h 1.25 mg/kg tiw after dialysis
	Maintenance Therapy: 5 mg/kg IV q24h	50–69 25–49 10–24 <10 or on hemodialysis	2.5 mg/kg q24h 1.25 mg/kg q24h 0.625 mg/kg q24h 0.625 mg/kg tiw after dialysis
Lamivudine	For HIV/HBV-coinfected patients: 150 mg bid or 300 mg daily	30–49 15–29 5–14 <5 or on hemodialysis	150 mg daily 150 mg x 1, then 100 mg daily 150 mg x 1, then 50 mg daily 50 mg x 1, then 25 mg daily
Levofloxacin	500–750 mg PO daily		750–1000 mg 3x weekly, adjust dosing based on TDM may be considered
Aqueous penicillin G	Neurosyphilis or Ocular syphilis: 3–4 milion units (MU) IV q4h	10–50 <10 Hemodialysis	2–3 MU q4h 1 MU q4-6h 1 MU q4-6h
Quinidine glucuronate	324–972 mg PO q8–12h	<10 Hemodialysis	75% of normal dose 75% of normal dose, schedule timing of dose after dialysis
Quinine sulfate	650 mg PO q8h for 3–7 days	10–50 <10	q8–12h or 75% of normal dose q24h
Ribavirin	1,000–1,200 mg/day in 2 divided doses (based on weight)	<50	Not recommended
Rifabutin	300 mg daily (or adjustment based on drug-drug interaction)	<30	Usually, no dosage change is necessary, some suggest 50% of dose or may consider TDM*
Streptomycin	15 mg/kg IM or IV q24h or 25 mg/kg tiw IM or IV		25 mg/kg tiw initially, adjust to achieve target peak concentration while allowing sufficient time for clearance. TDM is recommended
Sulfamethoxazole/ trimethoprim	15–20 mg/kg/day (of TMP) IV or PO in 3–4 divided doses	15–30 <15 Hemodialysis	5 mg/kg q6–8h x 48 hr, then 3.5–5 mg/kg q12h 7–10 mg/kg/day in 1–2 divided doses 7–10 mg/kg after dialysis

Note: To prevent underdosing, certain specialists prefer to use standard dose and measure drug levels.

TABLE 8. (*Continued*) Dosage adjustment in renal insufficiency

Drugs	Normal dose	Dosage adjustment in renal insufficiency	
		Creatinine clearance (mL/min)	Dose
Telbuvidine	600 mg PO daily	30–49 <30 (not on hemodialysis) Hemodialysis	600 mg q48h 600 mg q72h 600 mg q96h (dose after dialysis)
Tenofovir	For HIV (in HBV patients): 300 mg PO daily	30–49 10–29 End stage renal disease or hemodialysis	300 mg q48h 300 mg twice weekly 300 mg once weekly
Tetracycline	250 mg PO q6h x 7 days	10–49 <10 Hemodialysis	Adminster q12–24h Administer q24h Administer q24h, schedule timing of dose after dialysis
Valacyclovir	For herpes zoster 1 g PO tid	30–49 10–29 <10 Hemodialysis	1 g PO q12h 1 g PO q24h 500 mg PO q24h 500 mg PO q24h, schedule timing of dose after dialysis
Valganciclovir	900 mg PO bid (induction) 900 mg PO daily (maintenance)		Induction / Maintenance
		40–59 25–39 10–25 Hemodialysis	450 mg bid / 450 mg daily 450 mg daily / 450 mg qod 450 mg qod / 450 mg biw Not recommended / Not recommended
Voriconazole	IV dose: 6 mg/kg body weight g12h as loading dose, then 4 mg/kg q12h	≤50	Consider switching to PO dosing; SBECD vehicle might accumulate in patients with renal insufficiency

Definitions of abbreviations: bid = twice a day; IV=intravenous; q'n'h = every "n" hour; PO = by mouth; TDM = therapeutic drug monitoring; tid = three times daily; tiw = three times weekly; MU = million units; HSV/VZV = herpes simplex virus/varicella-zoster virus; HBV - hepatitis B virus.

TABLE 9. Summary of pre-clinical and human data on and indications for opportunistic infection drugs during pregnancy

Drug	FDA category	Pertinent animal reproductive and human pregnancy data	Recommended use during pregnancy
Acyclovir	B	No teratogenicity in mice, rats, rabbits at human levels. Large experience in pregnancy (>700 first-trimester exposures reported to registry); well-tolerated.	Treatment of frequent or severe symptomatic herpes outbreaks or varicella
Adefovir	C	Embryotoxic in mice; caused thymic lymphoid destruction in neonatal mice. Limited experience with human use in pregnancy.	Not recommended; report exposures during pregnancy to Antiretroviral Pregnancy Registry: http://www.APRegistry.com
Albendazole	C	Embryotoxic and teratogenic (skeletal malformations) in rats and rabbits but not in mice or cows. Limited experience in human pregnancy.	Not recommended. Primary therapy for microsporidosis in pregnancy should be antiretroviral therapy (ART).
Amikacin	C	Not teratogenic in animals. Theoretical risk for ototoxicty in fetus; reported with streptomycin but not amikacin.	Drug resistant tuberculosis, severe *Mycobacterium avium* (MAC) complex infections
Amoxicillin, amoxicillin/clavulanate, ampicillin/sulbactam	B	Not teratogenic in animals. Large experience in human pregnancy does not suggest an increase in adverse events.	Susceptible bacterial infections
Amphotericin B	B	Not teratogenic in animals or in human experience. Preferred over azole antifungals in first trimester if similar efficacy expected.	Documented invasive fungal disease
Antimonials, pentavalent (sodium stibogluconate, meglumine)	Not FDA approved	Antimony not teratogenic in rats, chicks, sheep. Three cases reported of use in human pregnancy in second trimester with good outcome. Labeled as contraindicated in pregnancy.	Therapy of visceral leishmaniasis not responsive to amphotericin B or pentamidine
Artesunate, artemether	Not FDA approved	Embryotoxicity, cardiovascular and skeletal anomalies in rats and rabbits. Limited human experience.	Pending more data, use for malaria in pregnancy only if other drugs not available or have failed.
Atovaquone	C	Not teratogenic in rats or rabbits, limited human experience	Alternate agent for *Pneumocystis jiroveci* pneumonia (PCP), *Toxoplasma gondii* infections
Azithromycin	B	Not teratogenic in animals. Moderate experience with use in human pregnancy does not suggest adverse events.	Preferred agent for MAC prophylaxis or treatment (with ethambutol), *Chlamydia trachomatis* infection in pregnancy.
Aztreonam	B	Not teratogenic in rats, rabbits. Limited human experience but other beta-lactam antibiotics have not been associated with adverse pregnancy outcomes.	Susceptible bacterial infections
Benznidazole	Not FDA approved	No animal studies. Increase in chromosomal aberrations in children with treatment; uncertain significance. No human pregnancy data.	Not indicated for chronic *Trypanosoma cruzi* in pregnancy. Seek expert consultation if acute or symptomatic infection in pregnancy requiring treatment.
Capreomycin	C	Increase in skeletal variants in rats. Limited experience in human pregnancy; theoretical risk for fetal ototoxicity.	Drug-resistant tuberculosis
Caspofungin	C	Embryotoxic, skeletal defects in rats, rabbits. No experience with human use.	Invasive *Candida* or *Aspergillus* infections refractory to amphotericin and azoles
Cephalosporins	B	Not teratogenic in animals. Large experience in human pregnancy has not suggested increase in adverse outcomes.	Bacterial infections; alternate treatment for MAC

TABLE 9. (*Continued*) Summary of pre-clinical and human data on and indications for opportunistic infection drugs during pregnancy

Drug	FDA category	Pertinent animal reproductive and human pregnancy data	Recommended use during pregnancy
Chloroquine	C	Associated with anophthalmia, micro-ophthalmia at fetotoxic doses in animals. Not associated with increased risk in human pregnancy at doses used for malaria.	Drug of choice for malaria prophylaxis and treatment of sensitive species in pregnancy
Cidofovir	C	Embryotoxic and teratogenic (meningocele, skeletal abnormalities) in rats and rabbits. No experience in human pregnancy.	Not recommended
Ciprofloxacin, other quinolones	C	Arthropathy in immature animals; not embryotoxic or teratogenic in mice, rats, rabbits, or monkeys. Approximately 400 cases of quinolone use in human pregnancy have not been associated with arthropathy or birth defects.	Severe MAC infections; multidrug-resistant tuberculosis, anthrax
Clarithromycin	C	Cardiovascular defects noted in one strain of rats and cleft palate in mice, not teratogenic in rabbits or monkeys. Two human studies, each with >100 first-trimester exposures, did not indicate increase in defects, but one study found an increase in spontaneous abortion.	Treatment or secondary MAC prophylaxis if other choices exhausted
Clindamycin	B	No concerns specific to pregnancy in animal or human studies	Treatment of anaerobic bacterial infections and used with quinine for chloroquine resistant malaria; alternate agent for secondary prophylaxis of *Toxoplasma* encephalitis
Clofazimine	C	Not teratogenic in mice, rats, or rabbits. Limited experience reported (19 cases); no anomalies noted but red-brown skin discoloration reported in several infants exposed throughout pregnancy.	No indications
Clotrimazole troches	C	Not teratogenic in animals at exposures expected from treatment of oral or vaginal *Candida*. No increase in adverse pregnancy outcomes with vaginal use.	Oral *Candida* infections and prophylaxis
Cycloserine	C	No data available from animal or human studies	Drug-resistant tuberculosis
Dapsone	C	No animal data. Limited human experience does not suggest teratogenicity; might displace bound bilirubin in the neonate, increasing the risk for kernicterus.	Alternate choice for primary or secondary PCP prophylaxis
Diphenoxylate	C	Limited animal and human data do not indicate teratogenicity	Symptomatic treatment of diarrhea
Doxycycline, other tetracyclines	D	Risk for hepatic toxicity increased with tetracyclines in pregnancy; staining of fetal bones and teeth contraindicate use in pregnancy	No indications
Emtricitabine	B	No concerns in pregnancy from limited animal and human data	As part of combination antiretroviral regimen for treatment of HIV, hepatitis B. Report exposures during pregnancy to Antiretroviral Pregnancy Registry: http://www.APRegistry.com.

TABLE 9. (*Continued*) Summary of pre-clinical and human data on and indications for opportunistic infection drugs during pregnancy

Drug	FDA category	Pertinent animal reproductive and human pregnancy data	Recommended use during pregnancy
Entecavir	C	Animal data do not suggest teratogenicity at human doses; no experience in human pregnancy.	Not indicated. Use antiretroviral agents active against both HIV and hepatitis B. Report exposures during pregnancy to Antiretroviral Pregnancy Registry: http://www.APRegistry.com.
Erythromycin	B	Hepatotoxicity with erythromycin estolate in pregnancy; other forms acceptable; no evidence of teratogenicity	Bacterial and chlamydial infections
Ethambutol	B	Teratogenic, at high doses, in mice, rats, rabbits. No evidence of teratogenicity in 320 cases of human use for treatment of tuberculosis.	Active tuberculosis and MAC treatment; avoid in first trimester if possible
Ethionamide	C	Increased rate of defects (omphalocele, exencephaly, cleft palate) in rats, mice, and rabbits with high doses; not seen with usual human doses. Limited human data.	Active tuberculosis; avoid in first trimester if possible
Famciclovir	B	No evidence of teratogenicity in rats or rabbits, limited human experience	Recurrent genital herpes and primary varicella infection. Report exposures during pregnancy to the Famvir Pregnancy Registry (1-888-669-6682).
Fluconazole	C	Abnormal ossification, structural defects in rats, mice at high doses. Case reports of rare pattern of craniofacial, skeletal and other abnormalities in five infants born to four women with prolonged exposure during pregnancy; no increase in defects seen in several series after single-dose treatment.	Single dose may be used for treatment of vaginal *Candida* though topical therapy preferred. Not recommended for prophylaxis during pregnancy. Can be used for invasive fungal infections after the first trimester; amphotericin B preferred in first trimester if similar efficacy expected.
Flucytosine	C	Facial clefts and skeletal defects in rats; no defects in mice, rabbits. No reports of use in first trimester of human pregnancy; might be metabolized to 5-fluorouracil, which is teratogenic in animals and possibly in humans.	Use after first trimester if indicated for life-threatening fungal infections
Fomivirsen	C	No animal studies; no data in human pregnancy. Intravitreous injection probably safe in pregnancy as minimal systemic levels.	Treatment of intraocular cytomegalovirus (CMV) infection
Foscarnet	C	Teratogenic in rats, rabbits. Single case report of use in human pregnancy in third trimester.	Alternate agent for treatment or secondary prophylaxis of life-threatening or sight-threatening CMV infection
Fumagillin	Not FDA approved	Caused complete litter destruction or growth retardation in rats, depending on when administered. No data in human pregnancy.	Topical solution may be used for ocular microsporidial infections
Ganciclovir, valganciclovir	C	Embryotoxic in rabbits and mice; teratogenic in rabbits (cleft palate, anophthalmia, aplastic kidney and pancreas, hydrocephalus). Case reports of safe use in human pregnancy after transplants, treatment of fetal CMV.	Treatment or secondary prophylaxis of life-threatening or sight-threatening CMV infection. Preferred agent for therapy in children
Granulocyte colony stimulating factor (GMCSF)	C	Not teratogenic in rats and rabbits. Case reports of use in human pregnancy without adverse effects.	Treatment of leucopenia
Imipenem	C	Not teratogenic in animals; limited human experience.	Serious bacterial infections
Imiquimod	B	No teratogenicity in rats and rabbits; eight case reports of human use, only two in first trimester	Because of limited experience, other treatment modalities such as cryotherapy or trichloracetic acid recommended for wart treatment during pregnancy

TABLE 9. (*Continued*) Summary of pre-clinical and human data on and indications for opportunistic infection drugs during pregnancy

Drug	FDA category	Pertinent animal reproductive and human pregnancy data	Recommended use during pregnancy
Influenza vaccine	C	Not teratogenic. Live vaccines, including intranasal influenza vaccine, are contraindicated in pregnancy.	All pregnant women should receive injectable influenza vaccine because of the increased risk of complications of influenza during pregnancy. HIV-infected women should be on ART before vaccination to limit potential increases in HIV RNA levels with immunization.
Interferons: alfa, beta, gamma	C	Abortifacient at high doses in monkeys, mice; not teratogenic in monkeys, mice, rats, or rabbits. Approximately 30 cases of use of interferon-alfa in pregnancy reported; 14 in first trimester without increase in anomalies; possible increased risk for intrauterine growth retardation.	Not indicated; treatment of hepatitis C should be delayed until after delivery
Isoniazid	C	Not teratogenic in animals. Possible increased risk for hepatotoxicity during pregnancy; prophylactic pyridoxine, 50 mg/day, should be administered to prevent neurotoxicity.	Active tuberculosis; prophylaxis for exposure or skin-test conversion
Itraconazole	C	Teratogenic in rats and mice at high doses. Case reports of craniofacial, skeletal abnormalities in humans with prolonged fluconazole exposure during pregnancy; no increase in defect rate noted among 156 infants born after first-trimester itraconazole exposure.	Only for documented systemic fungal disease, not prophylaxis. Consider using amphotericin B in first trimester if similar efficacy expected.
Kanamycin	D	Associated with club feet in mice, inner ear changes in multiple species. Hearing loss in 2.3% of 391 children after long-term in utero therapy.	Drug-resistant tuberculosis
Ketoconazole	C	Teratogenic in rats, increased fetal death in mice, rabbits. Inhibits androgen and corticosteroid synthesis; might affect fetal male genital development; case reports of craniofacial, skeletal abnormalities in humans with prolonged fluconazole exposure during pregnancy.	None
Lamivudine	C	Not teratogenic in animals. No evidence of teratogenicity with >1900 first-trimester exposures reported to Antiretroviral Pregnancy Registry.	HIV and Hepatitis B therapy, only as part of a combination antiretroviral regimen. Report exposures to Antiretroviral Pregnancy Registry: http://www.APRegistry.com.
Leucovorin (folinic acid)	C	Prevents birth defects of valproic acid, methotrexate, phenytoin, aminopterin in animal models. No evidence of harm in human pregnancies.	Use with pyrimethamine if use of pyrimethamine cannot be avoided
Linezolid	C	Not teratogenic in animals. Decreased fetal weight and neonatal survival at ~ human exposures. Limited human experience.	Serious bacterial infections
Loperamide	B	Not teratogenic in animals. No increase in birth defects among infants born to 89 women with first-trimester exposure.	Symptomatic treatment of diarrhea
Mefloquine	C	Animal data and human data do not suggest an increased risk of birth defects, but miscarriage and stillbirth might be increased.	Second line therapy of chloroquine-resistant malaria in pregnancy, if quinine/clindamycin not available or not tolerated. Weekly as prophylaxis in areas with chloroquine-resistant malaria.
Megalamine antimonate	Not FDA approved	See "Antimonials, pentvalent"	
Meripenam	B	Not teratogenic in animals; limited human experience	Serious bacterial infections

TABLE 9. (*Continued*) Summary of pre-clinical and human data on and indications for opportunistic infection drugs during pregnancy

Drug	FDA category	Pertinent animal reproductive and human pregnancy data	Recommended use during pregnancy
Metronidazole	B	Multiple studies do not indicate teratogenicity; one study with positive findings in rodents, guinea pigs. Studies in several hundred women with first trimester exposure found no increase in birth defects.	Anaerobic bacterial infections, bacterial vaginosis, trichomoniasis, giardiasis, amebiasis
Micafungin	C	Teratogenic in rabbits; no human experience	Not recommended
Miltefosine	Not FDA approved	Embryotoxic in rats, rabbits; teratogenic in rats. No experience with human use.	Not recommended
Nifurtimox	Not FDA approved	Not teratogenic in mice and rats. Increased chromosomal aberrations in children receiving treatment; uncertain significance. No experience in human pregnancy.	Not indicated in chronic infection; seek expert consultation if acute infection or symptomatic reactivation of *T. cruzi* in pregnancy
Nitazoxanide	B	Not teratogenic in animals; no human data	Severely symptomatic cryptosporidiosis after the first trimester
Para-amino salicylic acid (PAS)	C	Occipital bone defects in one study in rats; not teratogenic in rabbits. Possible increase in limb, ear anomalies in one study with 143 first trimester exposures; no specific pattern of defects noted, several studies did not find increased risk.	Drug-resistant tuberculosis
Paromomycin	C	Not teratogenic in mice and rabbits. Limited human experience, but poor oral absorption makes toxicity, teratogenicity unlikely.	Amebic intestinal infections, possibly cryptosporidiosis
Penicillin	B	Not teratogenic in multiple animal species. Experience with use in human pregnancy does not suggest teratogenicity, other adverse outcomes.	Syphilis, other susceptible bacterial infections
Pentamidine	C	Embryocidal but not teratogenic in rats, rabbits with systemic use. Limited systemic absorption with aerosol use; limited experience with systemic use in pregnancy.	Alternate therapy for PCP and leishmaniasis
Piperacillin-tazobactam	B	Not teratogenic in limited animal studies. Limited experience in pregnancy but penicillins generally considered safe.	Bacterial infections
Pneumococcal vaccine	C	No studies in animals or human pregnancy. Polysaccharide vaccines generally considered safe in pregnancy.	Initial or booster dose for prevention of invasive pneumococcal infections. HIV-infected pregnant women should be on highly-aggressive antiretroviral therapy before vaccination to limit potential increases in HIV ribonucleic acid levels with immunization.
Podophyllin, podofilox	C	Increased embryonic and fetal deaths in rats, mice but not teratogenic. Case reports of maternal, fetal deaths after use of podophyllin resin in pregnancy; no clear increase in birth defects with first-trimester exposure.	Because alternative treatments for genital warts in pregnancy are available, use not recommended; inadvertent use in early pregnancy is not indication for abortion
Posaconazole	C	Embryotoxic in rabbits; teratogenic in rats at similar to human exposures. No experience in human pregnancy.	Not recommended

TABLE 9. (*Continued*) Summary of pre-clinical and human data on and indications for opportunistic infection drugs during pregnancy

Drug	FDA category	Pertinent animal reproductive and human pregnancy data	Recommended use during pregnancy
Prednisone	B	Dose-dependent increased risk for cleft palate in mice, rabbits, hamsters; dose dependent increase in genital anomalies in mice. Human data inconsistent regarding increased risk for cleft palate. Risk for growth retardation, low birthweight might be increased with chronic use; monitor for hyperglycemia with use in third trimester.	Adjunctive therapy for severe PCP; multiple other non-HIV-related indications
Primaquine	C	No animal data. Limited experience with use in human pregnancy; theoretical risk for hemolytic anemia if fetus has G6PD deficiency.	Alternate therapy for PCP, chloroquine-resistant malaria
Proquanil	C	Not teratogenic in animals. Widely used in malaria-endemic areas with no clear increase in adverse outcomes.	Not recommended alone or in combination with atovaquone as primary therapy or prophylaxis of malaria
Pyrazinamide	C	Not teratogenic in mice. Limited experience with use in human pregnancy.	Active tuberculosis
Pyrimethamine	C	Teratogenic in mice, rats, hamsters (cleft palate, neural tube defects, and limb anomalies). Limited human data have not suggested an increased risk for birth defects; since folate antagonist, use with leucovorin.	Treatment and secondary prophylaxis of toxoplasmic encephalitis; alternate treatment of PCP
Quinidine gluconate	C	Generally considered safe in pregnancy; high doses associated with preterm labor. One case of fetal eighth nerve damage reported.	Alternate treatment of malaria, control of fetal arrhythmias
Quinine sulfate	C	High doses, often taken as an abortifacient, have been associated with birth defects, especially deafness, in humans and animals. Therapeutic doses have not been associated with an increased risk of defects in humans or animals. Monitor for hypoglycemia.	Treatment of chloroquine-resistant malaria
Ribavirin	X	Dose-dependent risk for multiple defects (craniofacial, central nervous system, skeletal, anophthalmia) in rats, mice, hamsters starting at below human doses. Reports of treatment during second half of pregnancy among nine women without incident; contraindicated in first trimester.	Contraindicated in early pregnancy; no clear indications in pregnancy
Rifabutin	B	Not teratogenic in rats and rabbits; no specific concerns for human pregnancy	Treatment or prophylaxis of MAC, active tuberculosis
Rifampin	C	Teratogenic in mice (cleft palate) and rats (spina bifida) but not in rabbits. No clear teratogenicity in humans.	Active tuberculosis
Sodium stibogluconate	Not FDA approved	See "Antimonials, pentavalent"	
Streptomycin	D	No teratogenicity in mice, rats, guinea pigs. Possible increased risk for deafness and VIII nerve damage; no evidence of other defects.	Alternate therapy for active tuberculosis
Sulfadiazine	B	Sulfonamides teratogenic in some animal studies. No clear teratogenicity among humans; potential for increased jaundice, kernicterus if used near delivery.	Secondary prophylaxis of toxoplasmic encephalitis

TABLE 9. (*Continued*) Summary of pre-clinical and human data on and indications for opportunistic infection drugs during pregnancy

Drug	FDA category	Pertinent animal reproductive and human pregnancy data	Recommended use during pregnancy
Telbivudine	B	Not teratogenic in rats, rabbits. Limited experience in human pregnancy.	Not indicated. Use antiretroviral agents active against both HIV and hepatitis B. Report exposures during pregnancy to Antiretroviral Pregnancy Registry: http://www.APRegistry.com.
Tenofovir	B	No evidence of birth defects in rats, rabbits, or monkeys at high doses; chronic administration in immature animals of multiple species at 6–50 times human doses has led to dose-specific bone changes ranging from decreased mineral density to severe osteomalacia and fractures. Clinical studies in humans (particularly children) show bone demineralization with chronic use; clinical significance unknown.	Possible component of ART regimen in pregnant women with hepatitis B coinfection requiring therapy. Report exposures during pregnancy to Antiretroviral Pregnancy Registry: http://www.APRegistry.com.
Trichloracetic acid, bichloracetic acid	Not rated	No studies. Used topically so no systemic absorption expected.	Topical therapy of non-cervical genital warts
Trifluridine	C	Not teratogenic in rats, rabbits. Minimal systemic absorption expected with topical ocular use.	Topical agent for treatment of ocular herpes infections
Trimethoprim-sulfamethoxazole (TMP-SMX)	C	Teratogenic in rats and mice. Possible increase in congenital cardiac defects, facial clefts, neural tube and urinary defects with first trimester use. Unclear if higher levels of folate supplementation lower risk. Potential for increased jaundice, kernicterus if used near delivery.	Therapy of PCP during pregnancy. Primary and secondary PCP prophylaxis in the second and third trimester; consider aerosolized pentamidine in first trimester. Recommend fetal ultrasound at 18–20 weeks after first trimester exposure.
Valacyclovir	B	Not teratogenic in mice, rats, and rabbits. Experience with valacyclovir in pregnancy limited; prodrug of acyclovir, which is considered safe for use in pregnancy.	Treatment of herpes simplex virus and varicella infections in pregnancy
Vancomycin	C	Not teratogenic in rats, rabbits. Limited human experience.	Serious bacterial infections
Voriconazole	D	Embryotoxic in rats, rabbits. Teratogenic in rats (cleft palate, hydronephrosis, ossification defects). No experience with human use.	Not recommended

TABLE 10. Comparative characteristics of TST with IGRAs*

Performance and operational characteristics	TST	RD1-based-IFN-γ assay	
		QFT®-Gold/ QFT®-Gold In-tube	T-SPOT™.*TB*
Estimated sensitivity (in patients with active TB)	~70% (lower in immunocompromised populations)	76%–80% (inadequate data in immunocompromised populations)	87%–88%
Estimated specificity (in healthy persons with no known TB disease/exposure)	56%–95%	97%	92%
Cross reactivity with BCG	Yes, if vaccinated after infancy	No	No
Cross reactivity with nontuberculous mycobacteria	Yes	Less likely	Less likely
Association between test positivity and subsequent risk of active TB during follow-up	Moderate-to-strong positive association	Insufficient evidence	Insufficient evidence
Correlation with *Mycobacterium tuberculosis* exposure	Yes	Yes (correlated better with exposure than TST in some head-to-head comparisons)	Yes (correlated better with exposure than TST in some head-to-head comparisons)
Benefits of treating test positives (based on randomized controlled trials)	Yes	No evidence	No evidence
Reliability (reproducibility)	Moderate	Limited evidence but might be high	Limited evidence but might be high
Inter-reader variability	Yes	No	Variation in counting spots (if read manually)
Boosting phenomenon	Yes	No	No
Potential for conversions and reversions	Yes	Yes	Yes
Adverse reactions	Yes	No	No
Patient visits to complete testing protocol	Two to four	One	One
Material costs	Low (TST antigen requires refrigeration)	Moderate (QFT®-Gold In-tube less complex than QFT®-Gold)	High
Sample processing and assay complexity	NA	Moderate	High
Laboratory infrastructure required	No	Yes	Yes
Time to obtain a result	48–72 hours	24–48 hours, longer if assays batched	24–48 hours, longer if assays batched
Trained personnel required	Yes	Yes	Yes

Definition of abbreviations: IGRA = Interferon gamma release assays; TST = tuberculin skin test; QFT-Gold = QuantiFERON®-TB Gold; IFNY = interferon-y; BCG = bacillus Calmette-Guerin; TB = tuberculosis.

TABLE 11. Cytology and histology terms for papanicolou smears and cervical, vaginal, and anal tissue samples

Cytology (Bethesda System 2001)*	Tissue histology Dysplasia)	Tissue histology (Cervical, vaginal, vulvar, and anal intraepithelial neoplasia system)
Negative for intraepithelial lesion of malignancy	Normal	Normal
Unsatisfactory	Unsatisfactory	Unsatisfactory
Atypical squamous cells – undetermined significance	No term	No term
Atypical squamous cells – cannot exclude high-grade squamous intraepithelial lesion (HSIL)	No term	No term
Low-grade squamous intraepithelial lesion (LSIL)	Mild	CIN I, VAIN I, VIN I, AIN I
HSIL	Moderate	CIN II, VAIN II, VIN II, AIN II
	Severe	CIN III, VAIN III, VIN III, AIN III
	CIS (carcinoma in situ)	CIN III, VAIN III, VIN III, AIN III
Carcinoma	Carcinoma	Carcinoma

Definition of abbreviations: CIN = cervical intraepithelial neoplasia; VAIN = vaginal intraepithelial neoplasia; VIN - vulvar intraepithelial neoplasia; AIN = anal intraepithelial neoplasia.

* Adapted from the Advisory Committee on Immunization Practices (ACIP) Adult Immunization Schedule. For detailed information on immunization against influenza, pneumococcal disease, hepatitis B, human papillomavirus, varicella, and hepatitis A, see disease-specific sections in the text and in Table 1. For information on immunization against tetanus, diphtheria, pertussis, measles, mumps, rubella, and meningococcal disease, refer to recommendations of the ACIP (www.cdc.gov/vaccines/pubs/ACIP-list.htm).

† Covered by the Vaccine Injury Compensation Program.

Appendix

Recommendations to Help Patients Avoid Exposure to or Infection from Opportunistic Pathogens*

Sexual Exposures

Male latex condoms, when used consistently and correctly during every act of sexual intercourse, are highly effective in preventing the sexual transmission of HIV and can reduce the risk for acquiring other sexually transmitted infections, including syphilis, chlamydia, gonorrhea, and trichomoniasis. Condom use might reduce the risk for transmission of herpes simplex virus and human papillomavirus **(AII)**, although data are more limited. Data regarding the use and efficacy of female condoms are limited **(BIII)**. Spermacides containing nonoxynol-9 (N-9) are not effective for HIV/STD prevention and should not be used as a microbicide or lubricant during vaginal or anal intercourse **(EII)**.

As with many non-sexually transmitted opportunistic infections, intercurrent infections with sexually transmitted pathogens (especially pathogens that cause genital ulcers such as herpes simplex, syphilis, and chancroid) can stimulate increases in HIV viral load and consequent declines in $CD4^+$ count. Furthermore, acquisition of STDs by HIV-infected patients indicates participation in high-risk sexual behavior capable of transmitting HIV to others, the risk for which is substantially increased in the presence of genital tract inflammation (e.g., from gonorrhea or chlamydia) and genital ulcer disease (e.g., HSV-2 infection, syphilis) (*1-5*). All patients, including patients who are asymptomatic, should be screened at least once for STDs. Screening should include testing for syphilis **(AII)**, trichomoniasis in women **(AII)**, urogenital gonorrhea and chlamydia **(BII)**, and oral and rectal gonorrhea and chlamydia for patients reporting receptive sex at these anatomic sites **(BII)** (*6,7*). Nucleic acid amplification testing methods can be more sensitive and specific than traditional culture methods and might be more acceptable to patients. Detailed recommendations for STD testing in HIV-infected persons can be found at the following site: http://www.cdc.gov/mmwr/preview/mmwrhtml/rr5212a1.htm. For all sexually active patients, STD screening should be repeated at least annually and whenever a patient reports high-risk sexual behaviors or symptoms **(BIII)**. In addition to identifying and treating STDs, providers should screen HIV-infected patients for risk behaviors; communicate prevention messages; discuss sexual and drug-use behaviors; positively reinforce safer behaviors; refer patients for services such as substance abuse treatment; and facilitate partner notification, counseling, and testing **(AII)**.

Patients should avoid sex practices that might result in oral exposure to feces (e.g., oral-anal contact) to reduce the risk for intestinal infections (e.g., cryptosporidiosis, shigellosis, campylobacteriosis, amebiasis, giardiasis, LGV serovars of *C. trachomatis* and hepatitis A) **(BIII)**. Latex condom use alone might not reduce the risk for acquiring these fecal-orally transmitted pathogens. Persons who wish to reduce their risk for exposure might consider using dental dams or similar barrier methods for oral-anal and oral-genital contact, changing condoms after anal intercourse, and wearing latex gloves during digital-anal contact. Frequent washing of hands and genitals with warm soapy water during and after activities that might bring these body parts in contact with feces might further reduce risk for illness **(CIII)**.

Hepatitis B vaccination is recommended for all susceptible (hepatitis B core antibody-negative) HIV-infected patients **(AII)**. Hepatitis A vaccination is recommended for all susceptible men who have sex with men, as well as others with indications for hepatitis A virus vaccine (e.g., injection-drug users, persons with chronic liver disease or who are infected with hepatitis B and/or C) **(AII)**.

Injection-Drug–Use Exposures

Injection-drug use is a complex behavior that puts HIV-infected persons at risk for hepatitis B virus and hepatitis C virus infection; additional, possibly drug-resistant strains of HIV; and other bloodborne pathogens. Providers should assess a person's readiness to change this practice and encourage activities to provide education and support directed at recovery. Patients should be counseled to stop using injection drugs **(AIII)** and to enter and complete substance abuse treatment, including relapse prevention programs (*8*) **(AIII)**.

For patients who continue to inject drugs, health-care providers should advise them to adhere to the following practices:

- Never reuse or share syringes, needles, water, or drug- preparation equipment; if injection equipment that has been used by other persons is shared, the implements should first be cleaned with bleach and water before use (**AI**).
- Use only sterile syringes obtained from a reliable source (e.g., pharmacies or syringe-exchange programs) (**BIII**).

* Letters and Roman numerals in parentheses indicate the strength of the recommendation and the quality of evidence supporting it (see Box in Introduction).

- Use sterile (e.g., boiled) water to prepare drugs, and if this is not feasible, use clean water from a reliable source (e.g., fresh tap water); use a new or disinfected container (i.e., cooker) and a new filter (i.e., cotton) to prepare drugs (**BIII**).
- Clean the injection site with a new alcohol swab before injection (**BIII**).
- Safely dispose of syringes after one use (**BIII**).

All susceptible injection-drug–users should be vaccinated against hepatitis B **(BII)** and hepatitis A **(BIII)**.

Environmental and Occupational Exposures

Certain activities or types of employment might increase the risk for exposure to tuberculosis. These include volunteer work or employment in health-care facilities, correctional institutions, and shelters for the homeless, and other settings identified as high risk by local health authorities. Decisions regarding whether to continue with such activities should be made in conjunction with a health-care provider and should be based on such factors as the patient's specific duties in the workplace, the prevalence of tuberculosis in the community, and the degree to which precautions designed to prevent the transmission of tuberculosis are taken in the workplace **(BIII)**. These decisions will affect the frequency with which the patient should be screened for tuberculosis. Day care providers and parents of children in child care are at increased risk for acquiring cytomegalovirus infection, cryptosporidiosis, and other infections (e.g., hepatitis A, giardiasis) from children. The risk for acquiring infection can be diminished by optimal hygienic practices (e.g., handwashing) after fecal contact (e.g., during diaper changing) and after contact with urine or saliva **(AII)**.

Occupations involving contact with animals (e.g., veterinary work and employment in pet stores, farms, or slaughterhouses) might pose a risk for cryptosporidiosis, toxoplasmosis, salmonellosis, campylobacteriosis, or *Bartonella* infection and other infections of concern to any immunocompromised host (e.g., leptospirosis, brucellosis, *Capnocytophaga* spp.). However, available data are insufficient to justify a recommendation against HIV-infected persons working in such settings.

Contact with young farm animals, specifically animals with diarrhea, should be avoided to reduce the risk for cryptosporidiosis **(BII)**. Since soils and sands can be contaminated with *Toxoplasma gondii* and *Cryptosporidium parvum*, persons who have extended contact with these materials (e.g., gardening; playing in or cleaning sandboxes) should wash their hands thoroughly with soap and water following exposure **(BIII)**. In areas where histoplasmosis is endemic, patients should avoid activities known to be associated with increased risk (e.g., creating dust when working with surface soil; cleaning chicken coops that are heavily contaminated with compost droppings; disturbing soil beneath bird-roosting sites; cleaning, remodeling or demolishing old buildings; and cave exploring) (**CIII**). In areas where coccidioidomycosis is endemic, when possible, patients should avoid activities associated with increased risk, including those involving extensive exposure to disturbed native soil (e.g., building excavation sites, during dust storms) (**CIII**).

Pet-Related Exposures

Health-care providers should advise HIV-infected persons of the potential risk posed by pet ownership. However, they should be sensitive to the possible psychological benefits of pet ownership and should not routinely advise HIV-infected persons to part with their pets **(DIII)**. Specifically, providers should advise HIV-infected patients of the following precautions (*9*).

General

Veterinary care should be sought when a pet develops diarrheal illness. If possible, HIV-infected persons should avoid contact with animals that have diarrhea **(BIII)**. A fecal sample should be obtained from animals with diarrhea and examined for *Cryptosporidium*, *Salmonella*, *Campylobacter*, and Shiga toxin-producing *Escherichia coli* **(BIII)**.

When obtaining a new pet, HIV-infected patients should avoid animals aged <6 months (or <1 year for cats) and specifically animals with diarrhea **(BIII)**. Because the hygienic and sanitary conditions in pet-breeding facilities, pet stores, and animal shelters are variable, patients should be cautious when obtaining pets from these sources. Stray animals should be avoided. Animals aged <6 months, and specifically those with diarrhea, should be examined by a veterinarian for *Cryptosporidium*, *Salmonella*, *Campylobacter*, and Shiga toxin-producing *Escherichia coli* **(BIII)**.

Patients should wash their hands after handling pets, including before eating, and avoid contact with pets' feces to reduce the risk for cryptosporidiosis, salmonellosis, campylobacteriosis, and *E. coli* infection **(BIII)**.

Patients should avoid all animal bite wounds to reduce the risk for infection. Patients should also not allow pets, particularly cats, to lick patients' open cuts or wounds. Patients should wash all animal bites, animal scratches, or wounds licked by animals promptly with soap and water **(CIII)** and seek medical attention **(BIII)**. A 3- to 7-day course of antimicrobial therapy might be recommended if the wounds are moderate or severe, demonstrate crush injury and edema, involve the bones of a

joint, involve a puncture of the skin near a joint, or involve a puncture of a joint directly **(CIII)**.

Cats

Patients should be aware that cat ownership increases their risk for toxoplasmosis and *Bartonella* infection, and enteric infections **(CIII)**. Patients who elect to obtain a cat should adopt or purchase an animal aged >1 year and in good health to reduce the risk for cryptosporidiosis, *Bartonella* infection, salmonellosis, campylobacteriosis, and *E. coli* infection **(BII)**.

Litter boxes should be cleaned daily, preferably by an HIV-negative, nonpregnant person; if HIV-infected patients perform this task, their hands should be washed thoroughly afterward to reduce the risk for toxoplasmosis **(BIII)**. To further reduce the risk for toxoplasmosis, HIV-infected patients should keep cats indoors, not allow them to hunt, and not feed them raw or undercooked meat **(BIII)**. Although declawing is not usually advised, patients should avoid activities that might result in cat scratches or bites to reduce the risk for *Bartonella* infection **(BII)**. Patients should also wash sites of cat scratches or bites promptly **(CIII)** and should not allow cats to lick patients' open cuts or wounds **(BIII)**.

Care of cats should include flea control to reduce the risk for *Bartonella* infection **(CIII)**. Testing cats for toxoplasmosis **(EII)** or *Bartonella* infection **(DII)** is not recommended.

Birds

Screening healthy birds for *Cryptococcus neoformans*, *Mycobacterium avium,* or *Histoplasma capsulatum* is not recommended **(DIII)**.

Other

Contact with reptiles (e.g., snakes, lizards, iguanas, and turtles) and chicks and ducklings should be avoided to reduce the risk for salmonellosis **(BIII)**. Gloves should be used during aquarium cleaning to reduce the risk for infection with *Mycobacterium marinum* **(BIII)**. Contact with exotic pets (e.g., nonhuman primates) should be avoided **(CIII)**.

Food- and Water-Related Exposures

HIV-infected persons should avoid eating certain foods, including foods that might contain raw eggs (e.g., certain preparations of hollandaise sauce, Caesar and other salad dressings, certain mayonnaises, uncooked cookie and cake batter, and eggnog); raw or undercooked poultry, meat, seafood (raw shellfish in particular); unpasteurized dairy products; unpasteurized fruit juice; and raw seed sprouts (e.g., alfalfa sprouts or mung bean sprouts). Poultry and meat are safest when adequate cooking is confirmed with a thermometer (165º F [74º F]). If a thermometer is not used, the risk for illness is decreased by eating poultry and meat that have no trace of pink. However, color change of meat (e.g., absence of pink) does not always correlate with internal temperature. Produce items should be washed thoroughly **(BIII)**; providers may wish to advise patients that produce is safest when cooked **(CIII)**.

Cross-contamination of foods should be avoided. Uncooked meats should not be allowed to come in contact with other foods; hands, cutting boards, counters, and knives and other utensils should be washed thoroughly after contact with uncooked foods **(BIII)**.

Although incidence of listeriosis is low, it is a serious disease that occurs unusually frequently among HIV-infected persons who are severely immunosuppressed. An immunosuppressed, HIV-infected person who wishes to reduce the risk for acquiring listeriosis as much as possible can do the following **(CIII)**:

- Avoid soft cheeses (e.g., feta, Brie, Camembert, blue-veined, and Mexican queso fresco cheese). Hard cheeses, processed cheeses, cream cheese, including slices and spreads, cottage cheese, or yogurt need not be avoided.
- Cook leftover foods or ready-to-eat foods (e.g., hot dogs) until steaming hot before eating.
- Avoid foods from delicatessen counters (e.g., prepared salads, meats, cheeses) or heat/reheat these foods until steaming before eating.
- Avoid refrigerated pâtés and other meat spreads, or heat/reheat these foods until steaming; canned or shelf-stable pâté and meat spreads need not be avoided.
- Avoid raw or unpasteurized milk, including goat's milk, or foods that contain unpasteurized milk or milk products.

Patients should not drink water directly from lakes or rivers because of the risk for

cryptosporidiosis, giardiasis, and toxoplasmosis **(AIII)**. Waterborne infection also might result from swallowing water during recreational activities. Patients should avoid swimming in water that is probably contaminated with human or animal waste and should avoid swallowing water during swimming **(BII)**.

During outbreaks or in other situations in which a community boil-water advisory is issued, boiling water for >1 minute will eliminate the risk for acquiring cryptosporidiosis **(AI)**. Using submicron, personal-use water filters (home/office types) or drinking bottled water might also reduce the risk **(CIII)**. Available data are inadequate to support a recommendation that all HIV-infected persons boil or otherwise avoid drinking tap water in nonoutbreak settings. However, persons who wish to take independent action to reduce their risk for waterborne cryptosporidiosis might take precautions similar to those recommended during outbreaks. Such decisions are best made in conjunction with a health-care provider. Persons

who opt for a personal-use filter or bottled water should be aware of the complexities involved in selecting the appropriate products, the lack of enforceable standards for destruction or removal of oocysts, product cost, and the difficulty of using these products consistently. Patients taking precautions to avoid acquiring cryptosporidiosis from drinking water should be advised that ice made from contaminated tap water also can be a source of infection **(BII)**. Such persons should be aware that fountain beverages served in restaurants, bars, theaters, and other public places also might pose a risk, because these beverages, and the ice they might contain, are usually made from tap water. Nationally distributed brands of bottled or canned carbonated soft drinks are safe to drink. Commercially packaged, noncarbonated soft drinks and fruit juices that do not require refrigeration until after they are opened (i.e., those that can be stored unrefrigerated on grocery shelves) also are safe. Nationally distributed brands of frozen fruit juice concentrate are safe if they are reconstituted by users with water from a safe source. Fruit juices that must be kept refrigerated from the time they are processed to the time of consumption might be either fresh (i.e., unpasteurized) or heat treated (i.e., pasteurized); only juices labeled as pasteurized should be considered free of risk from *Cryptosporidium* and other disease agents. Other pasteurized beverages and beers also are considered safe. No data are available concerning survival of *Cryptosporidium* oocysts in wine.

Travel-Related Exposures

Travel, specifically to developing countries, might result in substantial risks of the exposure of HIV-infected persons to opportunistic pathogens, especially for patients who are severely immunosuppressed. Health-care providers or specialists in travel medicine should be consulted to help patients plan itineraries **(BIII)**.

During travel to developing countries, HIV-infected persons are at a higher risk for foodborne and waterborne infections than they are in the United States. Foods and beverages, specifically raw fruits and vegetables, raw or undercooked seafood or meat, tap water, ice made with tap water, unpasteurized milk and dairy products, and items purchased from street vendors, might be contaminated. Items that are usually safe to consume include steaming hot foods, fruits that are peeled by the traveler, bottled (including carbonated) beverages, hot coffee or tea, beer, wine, and water brought to a rolling boil for ≥1 minute **(AII)**. Treating water with iodine or chlorine might not be as effective as boiling but can be used, perhaps in conjunction with filtration, when boiling is not practical **(BIII)**.

Waterborne infections might result from swallowing water during recreational activities. To reduce the risk for cryptosporidiosis, giardiasis, and toxoplasmosis, patients should avoid swallowing water during swimming and should not swim in water that might be contaminated (e.g., with sewage or animal waste) **(BII)**.

Antimicrobial prophylaxis for traveler's diarrhea is not recommended routinely for HIV-infected persons traveling to developing countries **(DIII)**. Such preventive therapy can have adverse effects and can promote the emergence of drug-resistant organisms. Nonetheless, studies (none involving an HIV-infected population) have reported that prophylaxis can reduce the risk for diarrhea among travelers. Under selected circumstances (e.g., those in which the risk for infection is high and the period of travel brief), the health-care provider and patient might weigh the potential risks and benefits and decide that antibiotic prophylaxis is warranted (**CIII**). For those persons to whom prophylaxis is offered, fluoroquinolones (e.g., ciprofloxacin [500 mg daily]) or rifaximin (200 mg daily) can be considered (**CIII**). Fluoroquinolones should not be administered to pregnant women and increasing resistance of bacterial enteric pathogens to fluoroquinolone might limit their future benefit for traveler's diarrhea. Prophylaxis with trimethoprim-sulfamethoxazole (TMP-SMX) (one double-strength tablet daily) also has been demonstrated to be effective, but resistance to this drug is widespread, and it is no longer recommended in many tropical areas.

HIV-infected travelers to developing countries should carry a sufficient supply of an antimicrobial agent to be taken empirically if diarrhea occurs **(BIII)**. One appropriate regimen is 500 mg of ciprofloxacin twice daily for 3–7 days. An alternative to fluoroquinolones in regions with fluoroquinolone resistance is azithromycin. Alternative antibiotics (e.g., azithromycin) should be considered as empirical therapy for use by pregnant women **(CIII)**. Travelers should consult a physician if their diarrhea is severe and does not respond to empirical therapy, if their stools contain blood, if fever is accompanied by shaking chills, or if dehydration occurs. Antiperistaltic agents (e.g., diphenoxylate and loperamide) are used for treating diarrhea; however, they should not be used by patients with high fever or with blood in the stool, and their use should be discontinued if symptoms persist >48 hours **(AII)**.

Travelers should be advised concerning other preventive measures appropriate for anticipated exposures (e.g., chemoprophylaxis for malaria, protection against arthropod vectors, treatment with immune globulin, and vaccination) **(AII)**. They should avoid direct contact of the skin with soil or sand (e.g., by wearing shoes and protective clothing and by using towels on beaches) in areas where fecal contamination of soil is likely **(BIII)**.

Live-virus vaccines should be avoided **(EII)**. One exception is measles vaccine, which is recommended for nonimmune

persons. However, measles vaccine is not recommended for persons who are severely immunosuppressed **(DIII)**; immune globulin should be considered for measles-susceptible, severely immunosuppressed persons who are anticipating travel to measles-endemic countries **(BIII)**. Another exception is varicella vaccine, which can be administered to asymptomatic nonimmunosuppressed adults who are susceptible to varicella virus infection **(BII)**. Inactivated (killed) poliovirus vaccine should be used instead of oral (live) poliovirus vaccine, which is contraindicated for HIV-infected persons. Persons at risk for exposure to typhoid fever should be administered an inactivated parenteral typhoid vaccine instead of the live-attenuated oral preparation. Yellow fever vaccine is a live-virus vaccine with uncertain safety and efficacy among HIV-infected persons. Travelers with asymptomatic HIV infection who cannot avoid potential exposure to yellow fever should be offered vaccination. If travel to a zone with yellow fever is necessary and vaccination is not administered, patients should be advised of the risk, instructed in methods for avoiding the bites of vector mosquitoes, and provided a vaccination waiver letter.

Killed and recombinant vaccines (e.g., influenza, diphtheria-tetanus, rabies, hepatitis A, hepatitis B, Japanese encephalitis, meningococcal vaccines) should usually be used for HIV-infected persons just as they would be used for non-HIV–infected persons anticipating travel **(BIII)**. Preparation for travel should include a review and updating of routine vaccinations, including diphtheria, tetanus, acellular pertussis, and influenza. Available cholera vaccine, which is not currently sold in the United States, is not recommended for travelers following a routine tourist itinerary, even if travel includes countries reporting cases of cholera **(DII)**.

Travelers should be informed regarding other area-specific risks and instructed in ways to reduce those risks **(BIII)**. Geographically focal opportunistic infections that pose an increased risk to HIV-infected persons include visceral leishmaniasis (a protozoan infection transmitted by the sandfly) and different fungal infections (e.g., *Penicillium marneffei* infection, coccidioidomycosis, and histoplasmosis). Several tropical and developing areas and some developed nations have high rates of tuberculosis.

CDC maintains a website accessible to travelers and their care providers at www.cdc.gov/travel and regularly publishes recommendations for prevention of disease while traveling (CDC Health Information for International Travel 2008, a.k.a. the Yellow Book). This information can be found at the same website, which allows users to locate prevention recommendations according to geographic destination and to find updates on international disease outbreaks that might pose a health threat to travelers. A detailed review of concerns faced by immunocompromised persons traveling abroad is available at this website and in the Yellow Book (Chapter 9) (*10*).

Acronyms

ABG	arterial blood gas
ABLC	amphotericin B liquid complex
ACG	atypical glandular cells
ACTG	AIDS Clinical Trials Group
ACTs	artemisinin-containing combination therapies
AFB	acid-fast bacillus (*pl.* bacilli)
AFP	alpha fetoprotein
AIN	anal intraepithelial neoplasia
ALT	alanine aminotransferase
Anti-HBc	anti-hepatitis B core antibody
Anti-HBs	anti-hepatitis B surface antibody
APR	Antiretroviral Pregnancy Registry
ARN	acute retinal necrosis
ART	antiretroviral therapy
ARV	antiretroviral
ASC-H	atypical squamous cells, cannot rule out high grade lesions
ASC-US	atypical squamous cells of undetermined significance
ASCCP	American Society for Colposcopy and Cervical Pathology
AST	aspartate aminotransferase
BA	bacillary angiomatosis
BCG	bacillus Calmette-Guérin
bDNA	branched DNA
CAP	community-acquired pneumonia
ccDNA	closed circular DNA
CDC	Centers for Disease Control and Prevention
CES-D	Center for Epidemiologic Studies Depression Scale
CIN	cervical intraepithelial neoplasia
CLEAR	Collaborative Exchange on Antifungal Research
CMV	cytomegalovirus
CNS	central nervous system
CPT score	Child-Pugh-Turcotte score
CSF	cerebrospinal fluid
CT	computed tomography
DNA	deoxyribonucleic acid
DOT	directly observed therapy
DRSP	drug-resistant *Streptococcus pneumoniae*
EBV	Epstein-Barr virus
EDTA	ethylenediaminetetraacetic acid
EGD	esophagogastroduodenoscopy
ELISA	enzyme-linked immunosorbent assay
EMB	ethambutol
ESLD	end-stage liver disease
EVR	early virologic response
FDA	Food and Drug Administration
FLAIR	fluid attenuated inversion recovery
HAART	highly active antiretroviral therapy
HAV	hepatitis A virus
HBeAG	hepatitis B virus e antigen
HBIG	hepatitis B virus immunoglobulin
HBsAg	hepatitis B virus surface antigen
HBV	hepatitis B virus
HCC	hepatocellular carcinoma
HCV	hepatitis C virus
HDV	hepatitis delta virus
HHV-6	human herpesvirus 6
HHV-7	human herpesvirus 7
HHV-8	human herpesvirus 8
HIV	human immunodeficiency virus
HIVMA	HIV Medical Association
HPV	human papillomavirus
HRA	high-resolution anoscopy
HSIL	high-grade squamous intraepithelial lesion
HSV-1	human herpes simplex virus type 1
HSV-2	human herpes simplex virus type 1
ICP	intracranial pressure
ICU	intensive care unit
IDSA	Infectious Diseases Society of America
IDU	intravenous- or injection-drug user
IFN	interferon
IgG	immunoglobulin G
IgM	immunoglobulin M
IGRA	interferon-gamma release assay
INH	isoniazid
INR	International Normalized Ratio
IRD	immune reconstitution disease
IRIS	immune reconstitution inflammatory syndrome
IRU	immune recovery uveitis
IV	intravenous
JCV	JC virus
KOH	potassium hydroxide
KS	Kaposi's sarcoma
KSHV	Kaposi's sarcoma-associated virus (aka HHV-8)
LEEP	loop electrosurgical excision procedure
LSIL	low-grade squamous intraepithelial lesion

LTBI	latent tuberculosis infection
MAC	*Mycobacterium avium* complex
MCD	Multicentric Castleman's disease
MDR	multidrug resistant (aka multiple drug-resistant)
MELD	Model for End-stage Liver Disease
MRI	magnetic resonance imaging
MSM	men who have sex with men
MTCT	mother-to-child transmission
MU	million units
NAA	nucleic acid amplification
NEP	needle exchange program
NIH	National Institutes of Health
NNRTI	non-nucleoside reverse transcriptase inhibitor
NRTI	nucleoside reverse transcriptase inhibitor
OARAC	Office of AIDS Research Advisory Council
OI	opportunistic infection
PCP	*Pneumocystis* pneumonia (formerly *P. carinii* [now *jirovecii*] pneumonia)
PCR	polymerase chain reaction
pegIFN	pegylated interferon
PEL	primary effusion lymphoma
PET	positron emission tomography
PI	protease inhibitor
PML	progressive multifocal leukoencephalopathy
PORN	progressive outer retinal necrosis
PPD	purified protein derivative
PPV	polysaccharide pneumococcal vaccine
PZA	pyrazinamide
RBV	ribavirin
RIF	rifampin
RFB	rifabutin
RNA	ribonucleic acid
RPR	rapid plasma reagin
RRP	recurrent respiratory papillomatosis
RT-PCR	reverse transcriptase-polymerase chain reaction
SAAG	serum-ascites albumin gradient
SBP	spontaneous bacterial peritonitis
SIRS	systemic inflammatory response syndrome
SLE	systemic lupus erythematosus
SP	sulfadoxine-pyrimethamine
SPECT	single-photon emission computed tomography
SVR	sustained virologic response
TB	tuberculosis
TE	*Toxoplasma gondii* encephalitis
TMP-SMX	trimethoprim-sulfamethoxazole
TSH	thyroid stimulating hormone
TST	tuberculin skin test
VAIN	vaginal intraepithelial neoplasia
VDRL	Venereal Disease Research Laboratory
VIN	vulvar intraepithelial neoplasia
VZV	varicella-zoster virus
WBC	white blood cell
WHO	World Health Organization
XDR	extensively drug resistant
YMDD	tyrosine-methionine-aspartate-aspartate

DHHS Panel on Guidelines for the Prevention and Treatment of Opportunistic Infections in HIV-Infected Adults and Adolescents, June 18, 2008

Editors, John T. Brooks, MD, Centers for Disease Control and Prevention, DHHS, Atlanta, GA, Alice Pau, PharmD, National Institutes of Health, DHHS, Bethesda, MD

Working Groups

Introduction, Leaders, Jonathan E. Kaplan, MD, Centers for Disease Control and Prevention, DHHS, Atlanta, GA, Constance Benson, MD, University of California San Diego, CA, John T. Brooks, MD and Judith Currier, MD, University of California Los Angeles, CA

Pneumocystis **Pneumonia, Leader,** Joseph Kovacs, MD, National Institutes of Health, DHHS, Bethesda, MD, **Members,** Hansjakob Furrer, MD, University Hospital and University of Bern, Switzerland, Laurence Huang, MD, San Francisco General Hospital, San Francisco, CA, Alison Morris, MD,MS, University of Pittsburgh Medical School, Pittsburgh, PA, Caryn G. Morse, MD, National Institutes of Health, DHHS, Bethesda, MD

Toxoplasma gondii **Encephalitis, Leader,** Joseph Kovacs, MD, National Institutes of Health, DHHS, Bethesda, MD, **Members,** Letha Healey, MD, National Institutes of Health, DHHS, Bethesda, MD, Daniel Podzamczer, MD, Hospital Universitari de Bellvitge, Spain, José Miró, MD, PhD, Hospital Clinic- IDIBAPS. University of Barcelona, Spain

Cryptosporidiosis, Bacterial Enteric Infections, Leader, Timothy Flanigan, MD, Brown Medical School, Providence, RI, **Members,** John T. Brooks, MD, Centers for Disease Control and Prevention, DHHS, Atlanta, GA, Cynthia L. Sears, MD, Johns Hopkins School of Medicine, Baltimore, MD, Christine Wanke, MD, Tufts University School of Medicine, Boston, MA, Clinton White, MD, University of Texas Medical Branch, Galveston, TX

Microsporidiosis, Leader, Louis Weiss, MD, MPH, Albert Einstein College of Medicine, Bronx, NY, **Members,** Elizabeth S. Didier, PhD, Tulane National Primate Research Center, Covington, LA, Caspar Franzen, MD, Universität Regensburg, Germany,

Mycobacterium tuberculosis **Infection and Disease, Leaders,** Alyssa Finlay, MD, Centers for Disease Control and Prevention, DHHS, Atlanta, GA, M. Elsa Villarino, MD, Centers for Disease Control and Prevention, DHHS, Atlanta, GA, **Members,** Hansjakob Furrer, MD, University Hospital and University of Bern, Switzerland, José M. Miró, MD, PhD, Hospital Clinic- IDIBAPS. University of Barcelona, Spain, Payam Nahid, MD, MPH, University of California San Francisco at San Francisco General Hospital, CA, Kent Sepkowitz, MD, Memorial Sloan Kettering Cancer Center, New York, NY, Sophia Siddiqui, MD, National Institutes of Health, DHHS, Bethesda, MD

Disseminated *Mycobacterium avium* Complex Disease, Leader, Fred Gordin, MD, Veterans Affairs Medical Center, Washington, DC, **Members,** David Cohn, MD, Denver Public Health, Denver, CO, Judith Currier, MD, University of California Los Angeles, CA, Susan Dorman, MD, Johns Hopkins University School of Medicine, Baltimore, MD, Robert Horsburgh, MD, Boston University School of Public Health, Boston, MA

Bacterial Respiratory Disease, Leader, Laurence Huang, MD, San Francisco General Hospital, San Francisco, CA, **Members,** Robert F. Miller, MD, University College London, United Kingdom, Alison Morris, MD, MS, University of Pittsburgh Medical School, Pittsburgh, PA, Michael S. Niederman, MD, Winthrop-University Hospital, Mineola, NY

Bacterial Enteric Infections, Leader, John T. Brooks, MD, Centers for Disease Control and Prevention, DHHS, Atlanta, GA, **Members,** Cynthia L. Sears, MD, Johns Hopkins School of Medicine, Baltimore, MD, Christine Wanke, MD, Tufts University School of Medicine, Boston, MA, Clinton White, MD, University of Texas Medical Branch, Galveston, TX

Bartonellosis, **Leader,** Jane Koehler, MD, University of California San Francisco, CA **Members,** Nesli Basgoz, MD, Massachusetts General Hospital, Harvard Medical School, Boston, MA, Lynn Guptill-Yoran, DVM, PhD, Purdue University School of Veterinary Medicine, West Lafayette, IN, James Oleske, MD, University of Medicine and Dentistry of New Jersey, Newark, NJ

Syphilis, Leader, Kimberly Workowski, MD, Emory University, Atlanta, GA, **Members,** Michael Augenbraun, MD, SUNY Downstate Medical Center, Brooklyn, NY, Edward Hook III, MD, University of Alabama, Birmingham, AL, Peter Leone, MD, University of North Carolina, Chapel Hill, NC, Anne Rompalo, MD, Johns Hopkins School of Medicine, Baltimore, MD, Bradley Stoner, MD, PhD, Washington University in St. Louis, St. Louis, MO, George Wendel, MD, University of Texas Southwestern Medical School, Dallas, TX

Mucocutaneous Candidiasis, Leader, Jack Sobel, MD, Wayne State University Medical Center, Detroit, MI, **Members,** Luis Ostrosky-Zeichner, MD, University of Texas Health Science Center, Houston, TX, Sanjay G. Revankar, MD, Wayne State University School of Medicine, Detroit, MI, Jose A. Vazquez, MD, Henry Ford Health System, Detroit, MI

Cryptococcosis, Histoplasmosis, Coccidomycosis, and Aspergillosis,, Leader, Neil Ampel, MD, Southern Arizona Veterans Affairs Health Care System, Tucson, AZ, **Members,** Carol A. Kauffman, MD, University of Michigan, Veterans Affairs Ann Arbor Healthcare System, MI, Peter G. Pappas, MD, University of Alabama School of Medicine, Birmingham, AL

Cytomegalovirus Disease, Leader, Paul D. Griffiths, MD, DSc, Royal Free and University College Medical School, United Kingdom, **Members,** Henry H. Balfour, Jr., MD, University of Minnesota, Minneapolis, MN, Douglas Jabs, MD, The Mount Sinai School of Medicine, New York, NY, Michael Polis, MD, National Institutes of Health, DHHS, Bethesda, MD, Stephen Spector, MD, University of California, San Diego, San Diego, CA

Herpes Simplex Virus Disease, HHV-6 and HHV-7, Varicella-Zoster Virus Diseases, and Human Herpesvirus-8 Disease, Leaders, John W. Gnann, Jr., MD, University of Alabama, Birmingham, AL, Anna Wald, MD, University of Washington, Seattle, WA, **Members,** Corey Casper, MD, MPH, University of Washington, Seattle, WA, David W. Kimberlin, MD, University of Alabama, Birmingham, AL, Peter Leone, MD, University of North Carolina, Chapel Hill, NC

Human Papillomavirus, Leader, Joel Palefsky, MD, University of California, San Francisco, San Francisco, CA, **Members,** Susan Cu-Uvin, MD, Brown Center for AIDS Research, Providence, RI, Eileen F. Dunne MD, MPH, Centers for Disease Control and Prevention, DHHS, Atlanta, GA, Kenneth H. Fife, MD, PhD, Indiana University School of Medicine, Indianapolis, IN, Kathleen Squires, MD, Jefferson Medical College, Philadelphia, PA, Howard D. Strickler, MD, MPH, Albert Einstein College of Medicine, Bronx, NY

Hepatitis B Virus Infection, Leader, Kenneth Sherman, MD, PhD, University of Cincinnati, Cincinnati, OH, **Members,** Barbara McGovern, MD, Tufts University School of Medicine, Jamaica Plain, MA, Mindie Nguyen, MD, MAS, Stanford University, Palo Alto, CA, Marion Peters, MD, University of California, San Francisco, San Francisco, CA

Hepatitis C Virus Infection, Leader, Mark Sulkowski, MD, Johns Hopkins University, Baltimore, MD, **Members,** Raymond Chung, MD, Massachusetts General Hospital, Boston, MA, Mamta Jain, MD, University of Texas Southwestern Medical Center, Dallas, TX, Margaret James Koziel, MD, Beth Israel Deaconess Medical Center, Boston, MA, Andrew Talal, MD, MPH, Weill Medical College of Cornell University, New York, NY

Progressive Multifocal Leukoencephalopathy/JC Virus Infection, Leader, Richard W. Price, MD, University of California San Francisco, San Francisco, CA, **Members,** Paola Cinque, MD, PhD , San Raffaele Scientific Institute, Milan, Italy, Igor J. Koralnik, MD, Beth Israel Deaconess Medical Center, Boston, MA, Christina M. Marra, MD, University of Washington, Seattle, WA, José M. Miró, MD, PhD, Hospital Clinic- IDIBAPS. University of Barcelona, Spain

Geographic OIs of Specific Consideration, Leaders, Monica Parise, MD, Centers for Disease Control and Prevention, DHHS, Atlanta, GA, Pacharee Kantipong, (penicilliosis), MD, Chiangrai Regional Hospital, Thailand, **Members,** Jorge Alvar, MD, World Health Organization, Geneva, Caryn Bern, MD, Centers for Disease Control and Prevention, DHHS , Atlanta, GA, Suwat Chariyalertsak, MD, DrPH, Chiang Mai University, Thailand, Barbara Herwaldt, MD, MPH, Centers for Disease Control and Prevention, DHHS, Atlanta, GA, James Maguire, MD, MPH, Brigham and Women's Hospital, Baltimore, MD, Anne Moore, MD, PhD, Centers for Disease Control and Prevention, DHHS, Atlanta, GA, Larry Slutsker, MD, MPH , Centers for Disease Control and Prevention, DHHS, Atlanta, GA, Khuanchai Suparatpinyo, MD, Chiang Mai University, Thailand, Jose Vazquez, MD, Henry Ford Health System, Detroit, MI, Murray Wittner, MD, PhD, Albert Einstein College of Medicine, Bronx, NY

Pregnancy, Leader, Heather Watts, MD, National Institutes of Health, DHHS, Rockville, MD, **Members,** Jean R. Anderson, MD, Johns Hopkins University, Baltimore, MD, Lynne Mofenson, MD, National Institutes of Health, DHHS, Rockville, MD.

Pharmacologic Issues/Tables, Leader, Alice Pau, PharmD, National Institutes of Health, DHHS, Bethesda, MD, **Members,** Ian R. McNicholl, PharmD , University of California, San Francisco, San Francisco, CA, Charles A. Peloquin, PharmD, National Jewish Medical and Research Center, Denver, CO, Paul J. Weidle, PharmD, MPH, Centers for Disease Control and Prevention, DHHS, Atlanta, GA

Immunizations, Leader, Gina Mootrey, DO, MPH, Centers for Disease Control and Prevention, DHHS, Atlanta, GA

Other Participants, Judith Aberg, MD, New York University, New York, NY, Miriam J. Alter, PhD, University of Texas Medical Branch, Galveston, TX, Roberto Badaro, MD, University of California, San Diego, La Jolla, CA, A. Cornelius Baker, Whitman-Walker Clinic, Washington, DC, John Bartlett, MD, Johns Hopkins University, Baltimore, MD, John Bennett, MD, National Institutes of Health, DHHS, Bethesda, MD, Pedro Cahn MD, PhD, Fundación Huesped, Argentina, Victoria Cargill, MD, National Institutes of Health, DHHS, Seattle, WA, Kenneth Castro, MD, Centers for Disease Control and Prevention, DHHS, Atlanta, GA, Richard E. Chaisson, MD, Johns Hopkins University, Baltimore, MD, Myron Cohen, MD, University of North Carolina, Chapel Hill, NC, Robert Eisinger, PhD, National Institutes of Health, DHHS, Bethesda, MD, Wafaa El-Sadr, MD, MPH, Harlem Hospital, New York, NY, Judith Feinberg, MD, University of Cincinnati, Cincinnati, OH, Kenneth A. Freedberg, MD, MSc, Harvard Medical School, Boston, MA, Jose M. Gatell, MD, PhD, Unidad de Enfermedades Infecciosas, Spain, Peter A. Gross, MD, Hackensack University Medical Center, Hackensack, NJ, Diane Havlir, MD, University of California, San Francisco, San Francisco, CA, Thomas M. Hooton, MD, University of Miami Miller School of Medicine, Miami, FL, Edward Janoff, MD, University of Colorado, Denver, CO, Grace John-Stewart, MD, Phd, MPH, University of Washington, Seattle, WA, Rupert Kaul, MD, PhD, University of Toronto, Canada, Mari Kitahata, MD, PhD, University of Washington, Seattle, WA, Jens Lundgren, MD, University of Copenhagen, Denmark, Scott McClelland, MD, MPH, University of Washington, Seattle, WA, Richard D. Moore, MD, MHS, Johns Hopkins University, Baltimore, MD, James Neaton, PhD, University of Minnesota, Minneapolis, MN, Benjamin J. Park, MD, Centers for Disease Control and Prevention, DHHS, Atlanta, GA, Thomas C. Quinn, MD, Johns Hopkins University, Baltimore, MD, David Rimland, MD, Veterans Administration Medical Center, Decatur, GA, Paul E. Sax, MD, Brigham and Women's Hospital, Boston, MA, Kathleen Squires, MD, Jefferson Medical College, Philadelphia, PA, Michael Tapper, MD, Lenox Hill Hospital, New York, NY, Chloe Thio, MD, Johns Hopkins University School of Medicine, Baltimore, MD, David Thomas, MD, Johns Hopkins University, Baltimore, MD, Cindy M. Weinbaum, MD, MPH, Centers for Disease Control and Prevention, DHHS, Atlanta, GA, Thomas C. Wright, Jr., MD, Columbia University Medical Center, New York, NY

The *Morbidity and Mortality Weekly Report (MMWR)* Series is prepared by the Centers for Disease Control and Prevention (CDC) and is available free of charge in electronic format. To receive an electronic copy each week, visit *MMWR*'s free subscription page at http://www.cdc.gov/mmwr/mmwrsubscribe.html. Electronic copy also is available from CDC's Internet server at *http://www.cdc.gov/mmwr* or from CDC's file transfer protocol server at *ftp://ftp.cdc.gov/pub/publications/mmwr.* Paper copy subscriptions are available through the Superintendent of Documents, U.S. Government Printing Office, Washington, DC 20402; telephone 202-512-1800.

Data in the weekly *MMWR* are provisional, based on weekly reports to CDC by state health departments. The reporting week concludes at close of business on Friday; compiled data on a national basis are officially released to the public on the following Friday. Data are compiled in the National Center for Public Health Informatics, Division of Integrated Surveillance Systems and Services. Address all inquiries about the *MMWR* Series, including material to be considered for publication, to Editor, *MMWR* Series, Mailstop E-90, CDC, 1600 Clifton Rd., N.E., Atlanta, GA 30333 or to *mmwrq@cdc.gov.*

All material in the *MMWR* Series is in the public domain and may be used and reprinted without permission; citation as to source, however, is appreciated.

Use of trade names and commercial sources is for identification only and does not imply endorsement by the U.S. Department of Health and Human Services.

References to non-CDC sites on the Internet are provided as a service to *MMWR* readers and do not constitute or imply endorsement of these organizations or their programs by CDC or the U.S. Department of Health and Human Services. CDC is not responsible for the content of these sites. URL addresses listed in *MMWR* were current as of the date of publication.

Recommendations and Reports
April 10, 2009 / Vol. 58 / RR-4

Continuing Education Activity Sponsored by CDC

Guidelines for Prevention and Treatment of Opportunistic Infections in HIV-Infected Adults and Adolescents

Recommendations from CDC, the National Institutes of Health, and the HIV Medicine Association of the Infectious Diseases Society of America

EXPIRATION — April 10, 2012

You must complete and return the response form electronically or by mail by **April 10, 2012**, to receive continuing education credit. If you answer all of the questions, you will receive an award letter for 3.25 hours Continuing Medical Education (CME) credit; 0.3 Continuing Education Units (CEUs); 3.25 contact hours Continuing Nursing Education (CNE) credit; 3.0 contact hours Certified Health Education Specialist (CHES) credit; or 0.3 CEUs Continuing Pharmacy Education (CPE) credit. If you return the form electronically, you will receive educational credit immediately. If you mail the form, you will receive educational credit in approximately 30 days. No fees are charged for participating in this continuing education activity.

INSTRUCTIONS

By Internet

1. Read this *MMWR* (Vol. 58, RR-4), which contains the correct answers to the questions beginning on the next page.
2. Go to the *MMWR* Continuing Education Internet site at http://www.cdc.gov/mmwr/cme/conted.html.
3. Select which exam you want to take and select whether you want to register for CME, CEU, CNE, CHES, or CPE credit.
4. Fill out and submit the registration form.
5. Select exam questions. To receive continuing education credit, you must answer all of the questions. Questions with more than one correct answer will instruct you to "Indicate all that apply."
6. Submit your answers no later than **April 10, 2012**.
7. Immediately print your Certificate of Completion for your records.

By Mail or Fax

1. Read this *MMWR* (Vol. 58, RR-4), which contains the correct answers to the questions beginning on the next page.
2. Complete all registration information on the response form, including your name, mailing address, phone number, and e-mail address.
3. Indicate whether you are registering for CME, CEU, CNE, CHES, or CPE credit.
4. Select your answers to the questions, and mark the corresponding letters on the response form. To receive continuing education credit, you must answer all of the questions. Questions with more than one correct answer will instruct you to "Indicate all that apply."
5. Sign and date the response form or a photocopy of the form and send no later than **April 10, 2012**, to
   Fax: 404-498-2388
   Mail: MMWR CE Credit
   CCHIS, Centers for Disease Control and Prevention
   1600 Clifton Rd, N.E., MS E-90
   Atlanta, GA 30333
6. Your Certificate of Completion will be mailed to you within 30 days.

ACCREDITATION

Continuing Medical Education (CME). CDC is accredited by the Accreditation Council for Continuing Medical Education (ACCME) to provide continuing medical education for physicians. CDC designates this educational activity for a maximum of 3.25 AMA PRA category 1 credits. Physicians should only claim credit commensurate with the extent of their participation in the activity.

Continuing Nursing Education (CNE). CDC is accredited as a provider of Continuing Nursing Education by the American Nurses Credentialing Center's Commission on Accreditation. This activity provides 3.25 contact hours.

Certified Health Education Specialist (CHES). CDC is a designated provider of continuing education contact hours (CECH) in health education by the National Commission for Health Education Credentialing, Inc. This program is a designated event for the CHES to receive 3.0 Category I contact hours in health education, CDC provider number GA0082.

Continuing Pharmacy Education (CPE). CDC is accredited by the Accreditation Council for Pharmacy Education as a provider of continuing pharmacy education. This program is a designated event for pharmacists to receive 0.3 CEUs in pharmacy education. The Universal Activity Number is 387-000-09-002-H02-P.

Continuing Education Unit (CEU). The CDC has been approved as an Authorized Provider by the International Association for Continuing Education and Training (IACET), 1760 Old Meadow Road, Suite 500, McLean, VA 22102. CDC is authorized by IACET to offer 0.3 CEU's for this program.

DEPARTMENT OF HEALTH AND HUMAN SERVICES
CENTERS FOR DISEASE CONTROL AND PREVENTION

Goal and Objectives

The goal of this report is to provide guidelines for clinicians and other health-care professionals regarding prevention and management of opportunistic illnesses (OIs) among HIV-1-infected adults and adolescents, including pregnant women. Upon completion of this educational activity, the reader should be able to 1) describe medications and their dosages for primary prophylaxis of OIs by chemoprophylaxis and vaccination, 2) describe methods for chronic suppressive therapy to prevent recurrence of OIs following treatment of acute illness, 3) describe recommendations for discontinuing primary prophylaxis and chronic suppressive therapy among persons whose CD4 cell count has increased as a result of antiretroviral therapy, 4) describe first-line medications and their dosages for the treatment of HIV-related OIs among adults and adolescents, and 5) describe recommendations for screening HIV-infected adults and adolescents for opportunistic infections.

To receive continuing education credits, please answer all of the following questions.

1. Primary prophylaxis to prevent acute infection in susceptible patients is recommended for all the following except…

A. *Pneumocystis jiroveci* (formerly *carinii*) pneumonia.
B. Disseminated *Mycobacterium avium* complex.
C. Mucocutaneous candidiasis.
D. Malaria for persons traveling to areas where malaria is endemic.
E. *Toxoplasma gondii* encephalitis.

2. Which of the following treatment regimens may be stopped if the patient's CD4 cell count rises to >100 cells/μL for >3 months due to antiretroviral therapy?

A. 100 mg of dapsone taken orally each day for prevention of *Pneumocystis jiroveci* (formerly *carinii*) pneumonia
B. One double-strength tablet of trimethoprim-sulfamethoxazole taken orally each day for prevention of *Toxoplasma gondii* in seropositive persons.
C. 400 mg of fluconazole taken orally each day for prevention of mucocutaneous candidiasis.
D. 300 mg of isoniazid and 50 mg of pyridoxine taken orally each day for persons with evidence of latent *Mycobacterium tuberculosis.*
E. 1200 mg of azithromycin taken orally once weekly for prevention of disseminated *Mycobacterium avium* complex.

3. For pregnant women in the first trimester of pregnancy, the preferred initial drug treatment for moderate to severe *Pneumocystis jiroveci* (formerly *carinii*) pneumonia is…

A. Dapsone 100 mg orally daily and TMP 15mg/kg/day orally in three divided doses.
B. Trimethoprim-sulfamethoxazole (TMP-SMX) [15–20 mg TMP and 75–100 mg. SMX]/kg/day given every 6–8 hours intravenously with adjunctive corticosteroid therapy according to the severity of illness.
C. Primaquine 15–30 mg (base) orally daily plus either clindamycin 600–900 mg. intravenously every 6–8 hours or clindamycin 300–450 mg orally very 6–8 hours with adjunctive corticosteroid therapy and after assessing G6PD status.
D. Aerosolized pentamidine 300 mg daily via Respirgard II™ nebulizer.
E. Atovaquone 750 mg orally twice daily with food.

4. Each of the following vaccinations is indicated for some or all HIV-infected men and women, except which of the following:

A. Inactivated influenza vaccination.
B. Varicella vaccination.
C. Human papillomavirus vaccination.
D. Hepatitis B vaccination.
E. Pneumococcal vaccination.

5. All of the following are recommended preferred therapy for the treatment of the associated infections except…

A. Oral ciprofloxacin at 750 mg twice daily for *Salmonella* gastroenteritis.
B. Oral clarithromycin at 500mg twice daily with oral ethambutol at 15mg/kg once daily for disseminated *Mycobacterium avium* complex.
C. Oral valacyclovir at 1,000 mg three time daily for varicella.
D. Intravenous amphotericin B deoxycholate at 0.6mg/kg daily for esophageal candidiasis.
E. Intravenous amphotericin B deoxycholate at 0.7mg/kg daily plus oral flucytosine at 100mg/kg daily administered in 4 divided doses for disseminated cryptococcosis.

6. Which of the following statements regarding syphilis is true?

A. Risk reduction counseling with a recommendation to notify and test sexual partners should be performed in all persons who have syphilis diagnosed at any stage.
B. Oral azithromycin is equally effective as intramuscular benzathine penicillin for primary, secondary or early latent infection.
C. Persons with late-latent syphilis in whom neurosyphilis has been ruled out by examination of cerebrospinal fluid should receive aqueous crystalline penicillin G at 18–24 million units per day administered intravenously as 3–4 million units IV every four hours for 10–14 days.
D. Probenecid should always be administered with penicillin for neurosyphilis.
E. Rates of syphilis among HIV-infected persons in the United States have remained stable for the past decade so that routine annual screening is now optional for sexually active patients without known contact with a syphilis-infected partner.

7. Which of the following actions is recommended to prevent exposure to OIs?

A. For cryptosporidiosis, routinely check pet dogs and cats for the parasite.
B. For listeriosis, do not eat soft cheeses.
C. For hepatitis B infection, do not travel to areas where it is endemic.
D. For histoplasmosis, avoid pet retiles.
E. For coccidiomycosis, do not use chlorinated pools frequented by infants.

8. Which of the following statements regarding viral hepatitis in HIV-infected persons is false?

A. Hepatitis A vaccination should be considered for all at-risk nonimmune patients.
B. Patients who are nonimmune to hepatitis C remain at risk for the infection.
C. Patients with viral hepatitis should avoid or limit alcohol consumption.
D. Patients with CD4 cell counts <200 cells/μL can be vaccinated for hepatitis B.
E. Treatment for hepatitis C infection is not indicated in patients with CD4 cell counts <50 cells/μL.

9. Immune reconstitution inflammatory syndrome (IRIS) has been reported in association with all of the following the infections after initiation of or a change in antiretroviral therapy (ART), except…

A. Cryptosporidial diarrhea.
B. Hepatitis B infection.
C. Progressive multifocal encephalopathy.
D. Mycobacterial infections.
E. Cryptococcosis.

10. Which of the following statements regarding herpes simplex virus (HSV) infection is false?

A. Consistent use of latex condoms can reduce sexual transmission of HSV between women and men.
B. Sexual transmission of HSV can occur even when overt lesions (genital or orolabial) are not present.
C. Prevention of recurrences of genital herpes with daily anti-HSV therapy in persons who have frequent or severe recurrences is recommended.
D. A treatment of choice for acyclovir-resistant HSV is valgancicolvir.
E. Acyclovir should not be given to pregnant women with genital HSV outbreaks due to the drug's substantial teratogenicity.

11. Which best describes your professional activities?
A. Physician.
B. Nurse.
C. Health educator.
D. Office staff.
E. Other.

12. I plan to use these recommendations as the basis for… (*indicate all that apply*):
A. Health education materials.
B. Insurance reimbursement policies.
C. Local practice guidelines.
D. Public policy.
E. Other.

13. Overall, the length of the journal article was…
A. Much to long.
B. A little to long.
C. Just right.
D. A little to short.
E. Much to short.

14. After reading this report, I am confident I can describe medications and their dosages for primary prophylaxis of OIs by chemoprophylaxis and vaccination.
A. Strongly agree.
B. Agree.
C. Undecided.
D. Disagree.
E. Strongly disagree.

15. After reading this report, I am confident I can describe methods for chronic suppressive therapy to prevent recurrence of OIs following treatment of acute illness.
A. Strongly agree.
B. Agree.
C. Undecided.
D. Disagree.
E. Strongly disagree.

16. After reading this report, I am confident I can describe recommendations for discontinuing primary prophylaxis and chronic suppressive therapy among persons whose CD4 cell count has increased as a result of antiretroviral therapy.
A. Strongly agree.
B. Agree.
C. Undecided.
D. Disagree.
E. Strongly disagree.

17. After reading this report, I am confident I can describe first line medications and their dosages for the treatment of HIV-related OIs among adults and adolescents.
A. Strongly agree.
B. Agree.
C. Undecided.
D. Disagree.
E. Strongly disagree.

18. After reading this report, I am confident I can describe recommendations for screening HIV infected adults and adolescents for opportunistic infections.
A. Strongly agree.
B. Agree.
C. Undecided.
D. Disagree.
E. Strongly disagree.

19. The learning outcomes (objectives) were relevant to the goal(s) of this report.
A. Strongly agree.
B. Agree.
C. Undecided.
D. Disagree.
E. Strongly disagree.

20. The instructional strategies used in this report (text, figure, and tables) helped me learn the material.
A. Strongly agree.
B. Agree.
C. Undecided.
D. Disagree.
E. Strongly disagree.

MMWR Response Form for Continuing Education Credit
April 10, 2009/Vol. 58/No. RR-4

Guidelines for Prevention and Treatment of Opportunistic Infections in HIV-Infected Adults and Adolescents

Recommendations from CDC, the National Institutes of Health, and the HIV Medicine Association of the Infectious Diseases Society of America

To receive continuing education credit, you must
1. provide your contact information (please print or type);
2. indicate your choice of CME, CME for nonphysicians, CEU, CNE, CHES, or CPE credit;
3. answer all of the test questions;
4. sign and date this form or a photocopy;
5. submit your answer form by **April 10, 2012.**
Failure to complete these items can result in a delay or rejection of your application for continuing education credit.

Check One
☐ CME Credit
☐ CME for nonphysicians Credit
☐ CEU Credit
☐ CNE Credit
☐ CHES Credit
☐ CPE Credit

Last Name (**print or type**) First Name

Street Address or P.O. Box

Apartment or Suite

City State ZIP Code

Phone Number Fax Number

Signature ***Date I Completed Exam***

21. The content was appropriate given the stated objective(s) of the course.
A. Strongly agree.
B. Agree.
C. Undecided.
D. Disagree.
E. Strongly disagree.

22. The authors demonstrated expertise in the subject matter.
A. Strongly agree.
B. Agree.
C. Undecided.
D. Disagree.
E. Strongly disagree.

23. Overall, the quality of the journal article was excellent.
A. Strongly agree.
B. Agree.
C. Undecided.
D. Disagree.
E. Strongly disagree.

24. The availability of CE credit influenced my decision to participate in this activity.
A. Strongly agree.
B. Agree.
C. Undecided.
D. Disagree.
E. Strongly disagree.
F. Not applicable.

25. These recommendations will improve the quality of my practice.
A. Strongly agree.
B. Agree.
C. Undecided.
D. Disagree.
E. Strongly disagree.

26. The *MMWR* format was conducive to leaning this content.
A. Strongly agree.
B. Agree.
C. Undecided.
D. Disagree.
E. Strongly disagree.

27. Do you feel this course was commercially biased?
(*Indicate yes or no; if yes, please explain in the space provided.*)
A. Yes.
B. No.

28. How did you learn about the continuing education activity?
A. Internet.
B. Advertisement (e.g., fact sheet, *MMWR* cover, newsletter, or journal).
C. Coworker/supervisor.
D. Conference presentation.
E. *MMWR* subscription.
F. Other.

Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents

January 10, 2011

Developed by the DHHS Panel on
Antiretroviral Guidelines for Adults
and Adolescents – A Working Group of the
Office of AIDS Research Advisory Council (OARAC)

How to Cite the Adult and Adolescent Guidelines:
Panel on Antiretroviral Guidelines for Adults and Adolescents. Guidelines for the use of antiretroviral agents in HIV-1-infected adults and adolescents. Department of Health and Human Services. January 10, 2011; 1–166. Available at **http://www.aidsinfo.nih.gov/ContentFiles/AdultandAdolescentGL.pdf**. Accessed [insert date] [insert page number, table number, etc. if applicable]

It is emphasized that concepts relevant to HIV management evolve rapidly. The Panel has a mechanism to update recommendations on a regular basis, and the most recent information is available on the **AIDS*info* Web site** (**http://aidsinfo.nih.gov**).

What's New in the Guidelines?

Key changes made to update the December 1, 2009, version of the guidelines are summarized below. Throughout the revised guidelines, significant updates are highlighted and fully discussed.

Introduction

The Panel emphasizes its recognition of the importance of clinical research in generating evidence to address unanswered questions related to the optimal safety and efficacy of antiretroviral therapy (ART). The Panel encourages both the development of protocols and patient participation in well-designed, Institutional Review Board (IRB)-approved clinical trials.

CD4 T-cell Count

The Panel recognizes that changes in CD4 cell count are seldom used in decision for ART changes in a patient on a suppressive ART regimen whose CD4 count is well above the threshold for opportunistic infection risk. In such patients, the Panel recommends that the CD4 count may be monitored less frequently, for example every 6 to 12 months (instead of every 3 to 6 months), unless there are changes in the patient's clinical status, such as new HIV-associated clinical symptoms or initiation of treatment with interferon, corticosteroids, or anti-neoplastic agents **(CIII)**.

Viral Load Testing

The Panel recognizes that low-level positive viral load results (typically <200 copies/mL) have been commonly reported with some viral load assays. For the purpose of patient monitoring, the Panel defines virologic failure as a confirmed viral load >200 copies/mL, which eliminates most cases of viremia caused by isolated blips or assay variability.

Drug-Resistance Testing

The Panel provides more specific recommendations on when to use genotypic testing to detect resistance to integrase strand transfer inhibitors (INSTIs).

- Because standard genotypic drug-resistance testing involves testing for mutations in the reverse transcriptase (RT) and protease (PR) genes, if transmitted INSTI resistance is a concern, providers may wish to supplement standard genotypic resistance testing with genotypic testing for resistance to this class of drugs **(CIII)**.
- In persons failing INSTI-based regimens, genotypic testing for INSTI resistance should be considered to determine whether to include a drug from this class in subsequent regimens **(BIII)**.

What to Start: Initial Combination Regimens for the Antiretroviral-Naïve Patient

Changes to the "What to Start" recommendations include the following:

- A regimen consisting of maraviroc (MVC) + zidovudine/lamivudine (ZDV/3TC) is now listed as an "Acceptable Regimen" because FDA approval of MVC for use in ART-naïve patients was based on the results of a randomized controlled trial using this regimen **(CI).**
- "MVC + tenofovir/emtricitabine (TDF/FTC)" and "MVC + abacavir (ABC)/3TC" have been added as "Regimens that may be acceptable but more definitive data are needed" **(CIII).**
- In response to a recent change to the Invirase® product label based on findings from a healthy volunteer study that reported significant PR and QT interval prolongations, ritonavir-boosted saquinavir (SQV/r)-based regimens have been moved from "Alternative PI-based Regimens" to "Regimens that are Acceptable but Should be Used with Caution."

Hepatitis B (HBV)/HIV Coinfection

This section has been revised to provide more specific recommendations for management of HIV patients coinfected with HBV, including recommendations for patients with 3TC/FTC-resistant HBV infection and for patients who cannot tolerate TDF-based regimens.

Mycobacterium Tuberculosis Disease with HIV Coinfection

Based on recent randomized controlled trials showing survival and clinical benefits of starting ART earlier in treatment-naïve patients with active tuberculosis (TB) disease, the Panel provides the following recommendations on when to start ART in patients who are receiving treatment for active TB but are not yet on ART.

- All HIV-infected patients with diagnosed active TB should be treated with ART **(AI)**.
- For patients with CD4 count <200 cells/mm^3, ART should be initiated within 2–4 weeks of starting TB treatment **(AI)**.
- For patients with CD4 count 200–500 cells/mm^3, the Panel recommends initiating ART within 2–4 weeks, or at least by 8 weeks after commencement of TB therapy **(AIII)**.
- For patients with CD4 count >500 cells/mm^3, most panel members also recommend starting ART within 8 weeks of TB therapy **(BIII)**.

Adverse Effects of Antiretroviral Agents

A new table format provides clinicians with a list of the most common and/or severe known antiretroviral (ARV)-associated adverse events listed by ARV drug class.

Additional Updates

The following sections and their relevant tables have also been updated:

- Coreceptor Tropism Assays
- Treatment Goals
- Initiating Antiretroviral Therapy in Treatment-Naïve Patients
- What Not to Use
- Virologic and Immunologic Failure (previously titled “Management of Patients with Antiretroviral Treatment Failure”)
- Regimen Simplification
- Exposure-Response Relationship and Therapeutic Drug Monitoring for Antiretroviral Agents
- Acute HIV Infection
- HIV and Illicit Drug Users (with new Table)
- HIV-2 Infection
- Drug Interactions (and Tables)
- Drug Characteristics Tables (Appendices)

Financial Disclosures for Members of DHHS Panel on Antiretroviral Guidelines for Adults and Adolescents available at: **http://aidsinfo.nih.gov/contentfiles/AA_FinancialDisclosures.pdf**

Guidelines Panel Members
DHHS Panel on Antiretroviral Guidelines for Adults and Adolescents

These Guidelines were developed by the Department of Health and Human Services (DHHS) Panel on Antiretroviral Guidelines for Adults and Adolescents (a Working Group of the Office of AIDS Research Advisory Council).

Panel Co-Chairs:
John G. Bartlett, Johns Hopkins University, Baltimore, MD
H. Clifford Lane, National Institutes of Health, Bethesda, MD

Executive Secretary:
Alice K. Pau, National Institutes of Health, Bethesda, MD

Scientific Members:

Jean R. Anderson	Johns Hopkins University, Baltimore, MD
John T. Brooks	Centers for Disease Control and Prevention, Atlanta, GA
Eric Daar	University of California–Los Angeles, Harbor-UCLA Medical Center, Los Angeles, CA
Steven G. Deeks	University of California–San Francisco, San Francisco, CA
Carlos del Rio	Emory University, Atlanta, GA
Robert T. Dodge	University of North Carolina, Chapel Hill, NC
Courtney V. Fletcher	University of Nebraska Medical Center, Omaha, NE
Gerald H. Friedland	Yale University School of Medicine, New Haven, CT
Joel E. Gallant	Johns Hopkins University, Baltimore, MD
Christopher M. Gordon	National Institutes of Health, Bethesda, MD
Roy M. Gulick	Weill Medical College of Cornell University, New York, NY
W. Keith Henry	Hennepin County Medical Center & University of Minnesota, Minneapolis, MN
Martin S. Hirsch	Massachusetts General Hospital and Harvard Medical School, Boston, MA
Michael D. Hughes	Harvard School of Public Health, Boston, MA
Bill G. Kapogiannis	National Institutes of Health, Bethesda, MD
Daniel R. Kuritzkes	Brigham and Women's Hospital & Harvard Medical School, Boston, MA
James Neaton	University of Minnesota, Minneapolis, MN
Richard W. Price	University of California–San Francisco, San Francisco, CA
Michael Saag	University of Alabama at Birmingham, Birmingham, AL
Paul E. Sax	Brigham and Women's Hospital & Harvard Medical School, Boston, MA
Mark Sulkowski	Johns Hopkins University, Baltimore, MD
Zelalem Temesgen	Mayo Clinic, Rochester, MN
Paul Volberding	University of California, San Francisco & VA Medical Center, San Francisco, CA
David A. Wohl	University of North Carolina, Chapel Hill, NC

Community Members:

Lei Chou	Treatment Action Group, New York, NY
Paul Dalton	San Francisco, CA
Heidi Nass	University of Wisconsin, Madison, WI
Jeffrey Taylor	Palm Springs, CA
Nelson Vergel	Program for Wellness Restoration, Houston, TX

Representatives from Department of Health and Human Services Agencies:

Victoria Cargill	National Institutes of Health
Laura Cheever	Health Resources and Services Administration
Jonathan Kaplan	Centers for Disease Control and Prevention
Henry Masur	National Institutes of Health
Lynne Mofenson	National Institutes of Health
Jeffrey Murray	Food and Drug Administration
Kimberly Struble	Food and Drug Administration

Non-Voting Observer:

Sarita Boyd	National Institutes of Health, SAIC-Frederick, Inc., NCI-Frederick, Frederick, MD

Acknowledgement:
The Panel would also like to acknowledge *Nina H. Lin, M.D., (Massachusetts General Hospital & Harvard Medical School, Boston, MA)* for her assistance in the preparation of the Guidelines.

Updated January 10, 2011

Introduction (Updated January 10, 2011)

Antiretroviral therapy (ART) for the treatment of human immunodeficiency virus (HIV) infection has improved steadily since the advent of potent combination therapy in 1996. New drugs have been approved that offer new mechanisms of action, improvements in potency and activity even against multidrug-resistant viruses, dosing convenience, and tolerability.

The Department of Health and Human Services (DHHS) Panel on Antiretroviral Guidelines for Adults and Adolescents (the Panel) is a working group of the Office of AIDS Research Advisory Council (OARAC). The primary goal of the Panel is to provide recommendations for HIV care practitioners based on current knowledge of antiretroviral (ARV) drugs used to treat adults and adolescents with HIV infection in the United States. The Panel reviews new evidence and updates recommendations when needed. The primary areas of attention have included baseline assessment, treatment goals, indications for initiation of ART, choice of the initial regimen in ART-naïve patients, drugs or combinations to be avoided, management of adverse effects and drug interactions, management of treatment failure, and special ART-related considerations in specific patient populations.

These guidelines generally represent the state of knowledge regarding the use of ARV agents. However, because the science evolves rapidly, the availability of new agents and new clinical data may change therapeutic options and preferences. Information included in these guidelines may not be consistent with approved labeling for the particular products or indications in question, and the terms "safe" and "effective" may not be synonymous with the Food and Drug Administration (FDA)-defined legal standards for product approval. The guidelines are updated frequently by the Panel (current and archived versions of the guidelines are available on the AIDS*info* Web site at **http://www.aidsinfo.nih.gov**). However, the guidelines cannot always keep pace with the rapid evolution of new data in this field, and they cannot provide guidance for all patients. Clinicians should exercise clinical judgment in management decisions tailored to unique patient circumstances.

The Panel recognizes the importance of clinical research in generating evidence to address unanswered questions related to the optimal safety and efficacy of ART. The Panel encourages both the development of protocols and patient participation in well-designed, Institutional Review Board (IRB)-approved clinical trials.

GUIDELINES DEVELOPMENT PROCESS

Table 1 provides an outline of the composition of the Panel and guidelines process.

Table 1. Outline of the Guidelines Development Process (Updated November 3, 2008)

Page 1 of 2

Topic	Comment
Goal of the guidelines	Provide guidance to HIV care practitioners on the optimal use of ARV agents for the treatment of HIV infection in adults and adolescents in the United States.
Panel members	The Panel is composed of more than 30 voting members who have expertise in HIV care and research. The U.S. government representatives include at least 1 representative from each of the following DHHS agencies: Centers for Disease Control and Prevention (CDC), FDA, Health Resource Services Administration (HRSA), and National Institutes of Health (NIH). These members are appointed by their respective agencies. Approximately 2/3 of the Panel members are nongovernmental scientific members. There are 4–5 community members with knowledge in HIV treatment and care. Members who do not represent U.S. government agencies are selected after an open announcement to call for nominations. Each member serves on the Panel for a 4-year term, with an option to be reappointed for an additional term. A list of the current members can be found on **Page vii** of this document.

Table 1. Outline of the Guidelines Development Process
Page 2 of 2

Topic	Comment
Financial disclosure	All members of the Panel submit a written financial disclosure annually reporting any association with manufacturers of ARV drugs or diagnostics used for management of HIV infections. A list of the latest disclosures is available on the AIDS*info* Web site (**http://aidsinfo.nih.gov/contentfiles/AA_Roster.pdf**).
Users of the guidelines	HIV treatment providers
Developer	Panel on Antiretroviral Guidelines for Adults and Adolescents—a working group of the OARAC
Funding source	Office of AIDS Research, NIH
Evidence collection	The recommendations in the guidelines are generally based on studies published in peer-reviewed journals. On some occasions, particularly when new information may affect patient safety, unpublished data presented at major conferences or prepared by the FDA and/or manufacturers as warnings to the public may be used as evidence to revise the guidelines.
Recommendation grading	As described in **Table 2**
Method of synthesizing data	Each section of the guidelines is assigned to a working group of Panel members with expertise in the area of interest. The members of the working group synthesize the available data and propose recommendations to the Panel. All proposals are discussed at monthly teleconferences and then voted on by the Panel before being endorsed as official recommendations.
Other guidelines	These guidelines focus on treatment for HIV-infected adults and adolescents. Separate guidelines outline the use of ART for other populations, such as pregnant women and children. These guidelines are also available on the AIDS*info* Web site (**http://www.aidsinfo.nih.gov**). There is a brief discussion of the management of women of reproductive age and pregnant women in this document. For a more detailed and up-to-date discussion on this group of women and other special populations, the Panel defers to the designated expertise offered by panels that have developed those guidelines.
Update plan	The Panel meets monthly by teleconference to review data that may warrant modification of the guidelines. Updates may be prompted by new drug approvals (or new indications, dosing formulations, or frequency), new significant safety or efficacy data, or other information that may have a significant impact on the clinical care of patients. For cases in which significant new data become available that may affect patient safety, a warning announcement with the Panel's recommendations may be made on the AIDS*info* Web site until appropriate changes can be made in the guidelines document. Updated guidelines are available on the AIDS*info* Web site (**http://www.aidsinfo.nih.gov**).
Public comments	After release of an update on the AIDS*info* Web site, the public is given a 2-week period to submit comments to the Panel. These comments are reviewed, and a determination is made as to whether revisions are indicated. The public may also submit comments to the Panel at any time at **contactus@aidsinfo.nih.gov**.

Basis for Recommendations

Recommendations in these guidelines are based upon scientific evidence and expert opinion. Each recommended statement is rated with a letter of **A**, **B**, or **C** that represents the strength of the recommendation and with a numeral **I**, **II**, or **III** that represents the quality of the evidence. (See **Table 2**.)

Table 2. Rating Scheme for Recommendations (Updated November 3, 2008)

Strength of Recommendation	Quality of Evidence for Recommendation
A: Strong recommendation for the statement **B:** Moderate recommendation for the statement **C:** Optional recommendation for the statement	**I:** One or more randomized trials with clinical outcomes and/or validated laboratory endpoints **II:** One or more well-designed, nonrandomized trials or observational cohort studies with long-term clinical outcomes **III:** Expert opinion

HIV Expertise in Clinical Care

Multiple studies have demonstrated that better outcomes are achieved in HIV-infected outpatients cared for by a clinician with HIV expertise *[1-6]*, which reflects the complexity of HIV infection and its treatment. Thus, appropriate training and experience, as well as ongoing continuing medical education (CME), are important components for optimal care. Primary care providers without HIV experience, such as those who provide service in rural or underserved areas, should identify experts in the region who will provide consultation when needed.

Baseline Evaluation (Updated January 10, 2011)

Each HIV-infected patient entering into care should have a complete medical history, physical examination, and laboratory evaluation and should be counseled regarding the implications of HIV infection. The goals of the initial evaluation are to confirm the presence of HIV infection, obtain appropriate baseline historical and laboratory data, ensure patient understanding about HIV infection and its transmission, and initiate care as recommended by established guidances such as the HIV primary care guidelines *[1]* and the guidelines for prevention and treatment of HIV-associated opportunistic infections *[2]*. Baseline information can then be used to define management goals and plans.

The following laboratory tests performed during initial patient visits can be used to stage HIV disease and to assist in the selection of antiretroviral (ARV) drug regimens:

- HIV antibody testing (if prior documentation is not available or if HIV RNA is below the assay's limit of detection) **(AI)**;
- CD4 T-cell count **(AI)**;
- Plasma HIV RNA (viral load) **(AI)**;
- Complete blood count, chemistry profile, transaminase levels, blood urea nitrogen (BUN) and creatinine, urinalysis, and serologies for hepatitis A, B, and C viruses **(AIII)**;
- Fasting blood glucose and serum lipids **(AIII)**; and
- Genotypic resistance testing at entry into care, regardless of whether ART will be initiated immediately **(AIII)**. For patients who have HIV RNA levels <500–1,000 copies/mL, amplification of virus for resistance testing may not always be successful **(BII)**.

In addition, other tests, including screening tests for sexually transmitted infections and tests for determining risk for opportunistic infections and need for prophylaxis, should be performed as recommended by HIV primary care and opportunistic infections guidelines *[1-2]*.

Patients living with HIV infection must often cope with multiple social, psychiatric, and medical issues that are best addressed through a patient-centered, multidisciplinary approach to the disease. The evaluation also must include assessment of high-risk behaviors, substance abuse, social support, mental illness, comorbidities, economic factors (e.g., unstable housing), medical insurance status and adequacy of coverage, and other factors that are known to impair adherence to treatment and to increase the risk of HIV transmission. Once evaluated, these factors should be managed accordingly.

Education about HIV risk behaviors and effective strategies to prevent HIV transmission should be provided at each patient visit. (See **Preventing Secondary Transmission of HIV**.)

Laboratory Testing for Initial Assessment and Monitoring While on Antiretroviral Therapy

(Updated January 10, 2011)

A number of laboratory tests are important for initial evaluation of HIV-infected patients upon entry into care, during follow-up if antiretroviral therapy (ART) has not been initiated, and prior to and after initiation or modification of therapy to assess virologic and immunologic efficacy of ART and to monitor for laboratory abnormalities that may be associated with antiretroviral (ARV) drugs. **Table 3** outlines the Panel's recommendations for the frequency of testing. As noted in the table, some of the tests may be repeated more frequently if clinically indicated.

Two surrogate markers are used routinely to assess the immune function and level of HIV viremia: CD4 T-cell count (CD4 count) and plasma HIV RNA (viral load). Resistance testing should be used to guide selection of an ARV regimen in both ART-naïve and ART-experienced patients; a viral tropism assay should be performed prior to initiation of a CCR5 antagonist; and HLA-B*5701 testing should be performed prior to initiation of abacavir (ABC). The rationale and utility of these laboratory tests are discussed below.

Table 3. Laboratory Monitoring Schedule for Patients Prior to and After Initiation of Antiretroviral Therapy (Updated January 10, 2011)

	Entry into care	Follow-up before ART	ART initiation or modification[1]	2–8 weeks post-ART initiation or modification	Every 3–6 months	Every 6 months	Every 12 months	Treatment failure	Clinically indicated
CD4 count	√	every 3–6 months	√		√	In clinically stable patients with suppressed viral load, CD4 count can be monitored every 6–12 months (see text)		√	√
Viral load	√	every 3–6 months	√	√[2]	√[3]			√	√
Resistance testing	√		√[4]					√	√
HLA-B*5701 testing			√ if considering ABC						
Tropism testing			√ if considering a CCR5 antagonist					√ if considering a CCR5 antagonist or for failure of CCR5 antagonist-based regimen	√
Hepatitis B serology[5]	√		√ may repeat if HBsAg (-) and HBsAb (-) at baseline						√
Basic chemistry[6]	√	every 6–12 months	√	√	√				√
ALT, AST, T. bilirubin	√	every 6–12 months	√	√	√				√
CBC with differential	√	every 3–6 months	√	√ if on ZDV	√				√
Fasting lipid profile	√	if normal, annually	√	√ consider 4–8 weeks after starting new ART		√ if abnormal at last measurement	√ if normal at last measurement		√
Fasting glucose	√	if normal, annually	√		√ if abnormal at last measurement	√ if normal at last measurement			√
Urinalysis[7]	√		√			√ if on TDF[8]	√		√
Pregnancy test			√ if starting EFV						√

[1]ARV modification may be done for treatment failure, adverse effects, or simplification.
[2]If HIV RNA is detectable at 2–8 weeks, repeat every 4–8 weeks until suppression to <200 copies/mL, then every 3–6 months.
[3]For adherent patients with suppressed viral load and stable clinical and immunologic status for >2–3 years, some experts may extend the interval for HIV RNA monitoring to every 6 months.
[4]For ART-naïve patients, if resistance testing was performed at entry into care, repeat testing is optional; for patients with viral suppression who are switching therapy for toxicity or convenience, resistance testing will not be possible and therefore is not necessary.
[5] If HBsAg is positive at baseline or prior to initiation of ART, TDF + (FTC or 3TC) should be used as part of ARV regimen to treat both HBV and HIV infections. If HBsAg and HBsAb are negative at baseline, hepatitis B vaccine series should be administered.
[6] Serum Na, K, HCO_3, Cl, BUN, creatinine, glucose (preferably fasting); some experts suggest monitoring phosphorus while on TDF; determination of renal function should include estimation of creatinine clearance using Cockcroft-Gault equation or estimation of glomerular filtration rate based on MDRD equation.
[7]For patients with renal disease, consult "Guidelines for the Management of Chronic Kidney Disease in HIV-Infected Patients: Recommendations of the HIV Medicine Association of the Infectious Diseases Society of America" *[1]*.
[8] More frequent monitoring may be indicated for patients with increased risk of renal insufficiency, such as patients with diabetes, hypertension, etc.

Acronyms: 3TC = lamivudine, ABC = abacavir, ALT = alanine aminotransferase, ART = antiretroviral therapy, AST = aspartate aminotranserase, CBC = complete blood count, EFV = efavirenz, FTC = emtricitabine, HBsAb = hepatitis B surface antibody, HBsAg = hepatitis B surface antigen, HBV = hepatitis B virus, MDRD = modification of diet in renal disease (equation), TDF = tenofovir, ZDV = zidovudine

CD4 T-CELL COUNT (Updated January 10, 2011)

The CD4 count serves as the major laboratory indicator of immune function in patients who have HIV infection. It is one of the key factors in deciding whether to initiate ART and prophylaxis for opportunistic infections, and it is the strongest predictor of subsequent disease progression and survival according to clinical trials and cohort studies *[1-2]*. A significant change (2 standard deviations) between two tests is approximately a 30% change in the absolute count or an increase or decrease in CD4 percentage by 3 percentage points.

- **Use of CD4 Count for Initial Assessment**. The CD4 count is one of the most important factors in the decision to initiate ART and/or prophylaxis for opportunistic infections. All patients should have a baseline CD4 count at entry into care **(AI)**. Recommendations for initiation of ART based on CD4 count are found in the **Initiating Antiretroviral Therapy in Antiretroviral-Naïve Patients** section of these guidelines.
- **Use of CD4 Count for Monitoring Therapeutic Response**. An adequate CD4 response for most patients on therapy is defined as an increase in CD4 count in the range of 50–150 cells/mm^3 per year, generally with an accelerated response in the first 3 months. Subsequent increases in patients with good virologic control show an average increase of approximately 50–100 cells/mm^3 per year for the subsequent years until a steady state level is reached *[3]*. Patients who initiate therapy with a low CD4 count or at an older age may have a blunted increase in their count despite virologic suppression.

Frequency of CD4 Count Monitoring. In general, CD4 counts should be monitored every 3–4 months to (1) determine when to start ART in untreated patients, (2) assess immunologic response to ART, and (3) assess the need for initiation or discontinuation of prophylaxis for opportunistic infections **(AI)**.

The CD4 cell count response to ART varies widely, but a poor CD4 response is rarely an indication for modifying a virologically suppressive ARV regimen. In patients with consistently suppressed viral loads who have already experienced ART-related immune reconstitution, the CD4 cell count provides limited information, and frequent testing may cause unnecessary anxiety in patients with clinically inconsequential fluctuations. Thus, for the patient on a suppressive regimen whose CD4 cell count has increased well above the threshold for opportunistic infection risk, the CD4 count can be measured less frequently than the viral load. In such patients, CD4 count may be monitored every 6 to 12 months, unless there are changes in the patient's clinical status, such as new HIV-associated clinical symptoms or initiation of treatment with interferon, corticosteroids, or anti-neoplastic agents **(CIII)**.

Factors that affect absolute CD4 count. The absolute CD4 count is a calculated value based on the total white blood cell (WBC) count and the percentages of total and CD4+ T lymphocytes. This absolute number may fluctuate among individuals or may be influenced by factors that may affect the total WBC and lymphocyte percentages, such as use of bone marrow–suppressive medications or the presence of acute infections. Splenectomy *[4-5]* or coinfection with human T-lymphotropic virus type I (HTLV-1) *[6]* may cause misleadingly elevated absolute CD4 counts. Alpha-interferon, on the other hand, may reduce the absolute CD4 number without changing the CD4 percentage *[7]*. In all these cases, CD4 percentage remains stable and may be a more appropriate parameter to assess the patient's immune function.

PLASMA HIV RNA TESTING (Updated January 10, 2011)

Plasma HIV RNA (viral load) should be measured in all patients at baseline and on a regular basis thereafter, especially in patients who are on treatment, because viral load is the most important indicator of response to antiretroviral therapy (ART) **(AI)**. Analysis of 18 trials that included more than 5,000 participants with viral load monitoring showed a significant association between a decrease in plasma viremia and improved clinical outcome *[1]*. Thus, viral load testing serves as a surrogate marker for treatment response *[2]* and can be useful in predicting clinical progression *[3-4]*. The minimal change in viral load considered to be statistically significant (2 standard deviations) is a threefold, or a 0.5 $\log_{10}$ copies/mL change.

Optimal viral suppression is generally defined as a viral load persistently below the level of detection (<20–75 copies/mL, depending on the assay used). However, isolated "blips" (viral loads transiently detectable at low levels, typically <400 copies/mL) are not uncommon in successfully treated patients and are not thought to represent viral replication or to predict virologic failure *[5]*. In addition, low-level positive viral load results (typically <200 copies/mL) appear to be more common with some viral load assays than others, and there is no definitive evidence that patients with viral loads quantified as <200 copies/mL using these assays are at increased risk for virologic failure *[6-8]*. For the purposes of clinical trials the AIDS Clinical Trials Group (ACTG) currently defines virologic failure as a confirmed viral load >200 copies/mL, which eliminates most cases of apparent viremia caused by blips or assay variability *[9]*. This definition may also be useful in clinical practice. (See **Virologic and Immunologic Failure**.)

For most individuals who are adherent to their antiretroviral (ARV) regimens and who do not harbor resistance mutations to the prescribed drugs, viral suppression is generally achieved in 12–24 weeks, even though it may take longer in some patients. Recommendations for the frequency of viral load monitoring are summarized below.

- **At Initiation or Change in Therapy.** Plasma viral load should be measured before initiation of therapy and preferably within 2–4 weeks, and not more than 8 weeks, after treatment initiation or after treatment modification **(BI)**. Repeat viral load measurement should be performed at 4–8-week intervals until the level falls below the assay's limit of detection **(BIII)**.
- **In Patients Who Have Viral Suppression but Therapy Was Modified Due to Drug Toxicity or Regimen Simplification.** Viral load measurement should be performed within 2–8 weeks after changing therapy. The purpose of viral load monitoring at this point is to confirm potency of the new regimen **(BIII)**.
- **In Patients on a Stable ARV Regimen.** Viral load should be repeated every 3–4 months or as clinically indicated **(BII)**. Some clinicians may extend the interval to every 6 months for adherent patients who have suppressed viral loads for more than 2–3 years and whose clinical and immunologic status is stable **(BIII)**.

Monitoring in Patients with Suboptimal Response. In addition to viral load monitoring, a number of additional factors, such as adherence to prescribed medications, altered pharmacology, or drug interactions, should be assessed. Patients who fail to achieve viral suppression should undergo resistance testing to aid in the selection of an alternative regimen, as discussed in **Drug Resistance Testing** and **Virologic and Immunologic Failure** **(AI)**.

DRUG-RESISTANCE TESTING (Updated January 10, 2011)

Panel's Recommendations:

- ***HIV drug-resistance testing is recommended for persons with HIV infection when they enter into care regardless of whether antiretroviral therapy (ART) will be initiated immediately or deferred (AIII). If therapy is deferred, repeat testing at the time of ART initiation should be considered (CIII).***
- ***Genotypic testing is recommended as the preferred resistance testing to guide therapy in antiretroviral (ARV)-naïve patients (AIII).***
- ***Standard genotypic drug-resistance testing in ARV-naïve persons involves testing for mutations in the reverse transcriptase (RT) and protease (PR) genes. If transmitted integrase strand transfer inhibitor (INSTI) resistance is a concern, providers may wish to supplement standard genotypic resistance testing with genotypic testing for resistance to this class of drug (CIII).***
- ***HIV drug-resistance testing should be performed to assist in the selection of active drugs when changing ARV regimens in persons with virologic failure and HIV RNA levels >1,000 copies/mL (AI). In persons with HIV RNA levels >500 but <1,000 copies/mL, testing may be unsuccessful but should still be considered (BII).***
- ***Drug-resistance testing should also be performed when managing suboptimal viral load reduction (AII).***
- ***In persons failing INSTI-based regimens, genotypic testing for INSTI resistance should be considered to determine whether to include a drug from this class in subsequent regimens (BIII).***
- ***Drug-resistance testing in the setting of virologic failure should be performed while the person is taking prescribed ARV drugs or, if not possible, within 4 weeks after discontinuing therapy (AII).***
- ***Genotypic testing is recommended as the preferred resistance testing to guide therapy in patients with suboptimal virologic responses or virologic failure while on first or second regimens (AIII).***
- ***Addition of phenotypic to genotypic testing is generally preferred for persons with known or suspected complex drug-resistance mutation patterns, particularly to protease inhibitors (PIs) (BIII).***
- ***Genotypic resistance testing is recommended for all pregnant women prior to initiation of therapy (AIII) and for those entering pregnancy with detectable HIV RNA levels while on therapy (AI).***

Rating of Recommendations: A = Strong; B = Moderate; C = Optional
Rating of Evidence: I = data from randomized controlled trials; II = data from well-designed nonrandomized trials or observational cohort studies with long-term clinical outcomes; III = expert opinion

Genotypic and Phenotypic Resistance Assays

Genotypic and phenotypic resistance assays are used to assess viral strains and inform selection of treatment strategies. Standard assays provide information on resistance to nucleoside reverse transcriptase inhibitors (NRTIs), non-nucleoside reverse transcriptase inhibitors (NNRTIs), and protease inhibitors (PIs). Testing for integrase and fusion inhibitor resistance can also be ordered separately from several commercial laboratories. No genotypic assays for assessing resistance to CCR5 antagonists are currently commercially available for clinical use in the United States. (See **Coreceptor Tropism Assays**.)

Genotypic Assays

Genotypic assays detect drug-resistance mutations present in relevant viral genes. Most genotypic assays involve sequencing of the RT and PR genes to detect mutations that are known to confer drug resistance. Genotypic assays that assess mutations in the integrase and gp41 (envelope) genes are also commercially available. Genotypic assays can be performed rapidly with results available within 1–2 weeks of sample collection. Interpretation of test results requires knowledge of the mutations that different ARV drugs select for and of the potential for cross resistance to other drugs conferred by certain mutations. The International AIDS Society-USA (IAS-USA) maintains a list of updated significant resistance-associated mutations in the RT, PR, integrase, and envelope genes (see **http://www.iasusa.org/resistance_mutations**) *[1]*. The Stanford University HIV Drug Resistance Database (**http://hivdb.stanford.edu**) also provides helpful guidance for interpreting genotypic resistance test results. Various tools are now available to assist the provider in interpreting genotypic test results *[2-5]*. Clinical trials have demonstrated the benefit of consultation with specialists in HIV drug resistance in improving virologic outcomes *[6]*.

Clinicians are thus encouraged to consult a specialist to facilitate interpretation of genotypic test results and the design of an optimal new regimen.

Phenotypic Assays

Phenotypic assays measure the ability of a virus to grow in different concentrations of ARV drugs. RT and PR gene sequences and, more recently, integrase and envelope sequences derived from patient plasma HIV RNA are inserted into the backbone of a laboratory clone of HIV or used to generate pseudotyped viruses that express the patient-derived HIV genes of interest. Replication of these viruses at different drug concentrations is monitored by expression of a reporter gene and is compared with replication of a reference HIV strain. The drug concentration that inhibits viral replication by 50% (i.e., the median inhibitory concentration [$IC]_{50}$) is calculated, and the ratio of the IC_{50} of test and reference viruses is reported as the fold increase in IC_{50} (i.e., fold resistance).

Automated phenotypic assays are commercially available with results reported in 2–3 weeks. However, phenotypic assays cost more to perform than genotypic assays. In addition, interpretation of phenotypic assay results is complicated by incomplete information regarding the specific resistance level (i.e., fold increase in IC_{50}) that is associated with drug failure, although clinically significant fold increase cutoffs are now available for some drugs *[7-11]*. Again, consultation with a specialist can be helpful for interpreting test results.

Further limitations of both genotypic and phenotypic assays include lack of uniform quality assurance for all available assays, relatively high cost, and insensitivity for minor viral species. Despite being present, drug-resistant viruses constituting less than 10%–20% of the circulating virus population will probably not be detected by available assays. This limitation is important because after drugs exerting selective pressure on drug-resistant populations are discontinued, a wild-type virus often re-emerges as the predominant population in the plasma. As a consequence, the proportion of virus with resistance mutations decreases to below the 10%–20% threshold *[12-14]*. For some drugs, this reversion to predominantly wild-type virus can occur in the first 4–6 weeks after drugs are stopped. Prospective clinical studies have shown that, despite this plasma reversion, reinstitution of the same ARV agents (or those sharing similar resistance pathways) is usually associated with early drug failure, and the virus present at failure is derived from previously archived resistant virus *[15]*. Therefore, resistance testing is of greatest value when performed before or within 4 weeks after drugs are discontinued **(AII)**. Because detectable resistant virus may persist in the plasma of some patients for longer periods of time, resistance testing beyond 4 to 6 weeks after discontinuation may still reveal mutations. However, the absence of detectable resistance in such patients must be interpreted with caution in designing subsequent ARV regimens.

Use of Resistance Assays in Clinical Practice (Table 4)

No definitive prospective data exist to support using one type of resistance assay over another (i.e., genotypic vs. phenotypic) in different clinical situations. In most situations genotypic testing is preferred because of the faster turnaround time, lower cost, and enhanced sensitivity for detecting mixtures of wild-type and resistant virus. However, for patients with a complex treatment history, results derived from both assays might provide critical and complementary information to guide regimen changes.

Use of Resistance Assays in Determining Initial Treatment

Transmission of drug-resistant HIV strains is well documented and associated with suboptimal virologic response to initial ART *[16-19]*. The likelihood that a patient will acquire drug-resistant virus is related to the prevalence of drug resistance in HIV-infected persons engaging in high-risk behaviors in the community. In the United States and Europe, recent studies suggest the risk that transmitted virus will be resistant to at least one ARV drug is in the range of 6%–16% *[20-25]*, with 3%–5% of transmitted viruses exhibiting resistance to drugs from more than one class *[16, 24]*.

If the decision is made to initiate therapy in a person with acute HIV infection, resistance testing at baseline will provide guidance in selecting a regimen to optimize virologic response. Therefore, resistance testing in this situation is recommended **(AIII)** and a genotypic assay is preferred **(AIII)**. In this setting, treatment initiation should not be delayed by pending resistance testing results. Once results are obtained, the treatment regimen can be modified if warranted by the results. (See **Acute HIV Infection**.) In the absence of therapy, resistant viruses may decline over

time to less than the detection limit of standard resistance tests but may still increase the risk of treatment failure when therapy is eventually initiated *[26-28]*. Therefore, if therapy is deferred, resistance testing during acute HIV infection should still be performed **(AIII)**. In this situation, the genotypic resistance test result might be kept on record for several years before it becomes clinically useful. Because it is possible for a patient to acquire drug-resistant virus (i.e., superinfection) between entry into care and initiation of ART, repeat resistance testing at the time treatment is started should be considered **(CIII)**.

Performing drug-resistance testing before ART initiation in patients with chronic HIV infection is less straightforward. The rate at which transmitted resistance-associated mutations revert to wild-type virus has not been completely delineated, but mutations present at the time of HIV transmission are more stable than those selected under drug pressure, and it is often possible to detect resistance-associated mutations in viruses that were transmitted several years earlier *[29-31]*. No prospective trial has addressed whether drug-resistance testing prior to initiation of therapy confers benefit in this population. However, data from several, but not all, studies suggest suboptimal virologic responses in persons with baseline mutations *[16-19, 32-34]*. In addition, a cost-effectiveness analysis of early genotypic resistance testing suggests that baseline testing in this population should be performed *[35]*. Therefore, resistance testing in chronically infected persons at the time of entry into HIV care is recommended **(AIII)**. Genotypic testing is generally preferred in this situation because of lower cost, more rapid turnaround time, ability to detect mixtures of wild-type and resistant virus, and the relative ease of interpretation **(AIII)**. If therapy is deferred, repeat testing just prior to initiation of ART should be considered because the patient may have acquired drug-resistant virus (i.e., superinfection) **(CIII)**.

Standard genotypic drug-resistance testing in ARV-naïve persons involves testing for mutations in the RT and PR genes. Although transmission of INSTI-resistant virus has rarely been reported, as use of INSTIs increases, the potential for transmission of INSTI-resistant virus may also increase. Therefore, providers may wish to supplement standard baseline genotypic resistance testing with genotypic testing for resistance to this class of drugs **(CIII).**

Use of Resistance Assays in the Event of Virologic Failure

Resistance assays are useful in guiding decisions for patients experiencing virologic failure while on ART. Several prospective studies assessed the utility of resistance testing in guiding ARV drug selection in patients with virologic failure. These studies involved genotypic assays, phenotypic assays, or both *[6, 36-42]*. In general, these studies found that early virologic response to salvage regimens was improved when results of resistance testing were available to guide changes in therapy, compared with responses observed when changes in therapy were guided only by clinical judgment. Additionally, one observational study demonstrated improved survival in patients with detectable HIV plasma RNA when drug-resistance testing was performed *[43]*. Thus, resistance testing appears to be a useful tool in selecting active drugs when changing ARV regimens for virologic failure in persons with HIV RNA >1,000 copies/mL **(AI)**. (See **Virologic and Immunologic Failure**.) In persons with >500 but <1,000 copies/mL, testing may be unsuccessful but should still be considered **(BII)**. Drug-resistance testing is not usually recommended in persons with a plasma viral load <500 copies/mL because resistance assays cannot be consistently performed given low HIV RNA levels **(AIII)**.

Resistance testing also can help guide treatment decisions for patients with suboptimal viral load reduction **(AII)**. Virologic failure in the setting of combination ART is, for certain patients, associated with resistance to only one component of the regimen *[44-46]*. In that situation, substituting individual drugs in a failing regimen might be possible, although this concept will require clinical validation. (See **Virologic and Immunologic Failure**.)

Genotypic testing is generally preferred for virologic failure or suboptimal viral load reduction in persons failing their first or second ARV drug regimen because of lower cost, faster turnaround time, and greater sensitivity for detecting mixtures of wild-type and resistant virus **(AIII)**. Addition of phenotypic to genotypic testing is generally preferred for persons with known or suspected complex drug-resistance mutation patterns, particularly to PIs **(BIII)**.

In patients failing INSTI-based regimens, testing for INSTI resistance should be considered to determine whether to include drugs from this class in subsequent regimens; genotypic testing is preferred **(BIII)**. Although it is not a drug-resistance assay, a coreceptor tropism assay should be performed whenever the use of a CCR5 antagonist is being considered **(AI)**. Coreceptor tropism testing should also be considered for patients who exhibit virologic failure on a CCR5 antagonist **(CIII)**. However, such testing may be of limited value because the absence of detectable CXCR4-

using virus does not exclude the possibility that CCR5 antagonist resistance may have developed. Assays for resistance to CCR5 inhibitors are not yet commercially available *[47]*. (See **Coreceptor Tropism Assays**.)

Use of Resistance Assays in Pregnant Women

In pregnant women, the goal of ART is to maximally reduce plasma HIV RNA to provide appropriate maternal therapy and prevent mother-to-child transmission (MTCT) of HIV. Genotypic resistance testing is recommended for all pregnant women prior to initiation of therapy **(AIII)** and for those entering pregnancy with detectable HIV RNA levels while on therapy **(AI)**. Phenotypic testing may provide additional information in those found to have complex drug-resistance mutation patterns, particularly to PIs **(BIII)**. Optimal prevention of perinatal transmission may require initiation of ART while results of resistance testing are pending. Once the results are available, the ARV regimen can be changed as needed.

Table 4. Recommendations for Using Drug-Resistance Assays (Updated January 10, 2011)

Clinical Setting/Recommendation	Rationale
Drug-resistance assay recommended	
In acute HIV infection: Drug-resistance testing is recommended regardless of whether ART is initiated immediately or deferred **(AIII)**. A genotypic assay is generally preferred **(AIII)**.	If ART is to be initiated immediately, drug-resistance testing will determine whether drug-resistant virus was transmitted. Test results will help in the design of initial regimens or to modify or change regimens if results are obtained subsequent to treatment initiation. Genotypic testing is preferable to phenotypic testing because of lower cost, faster turnaround time, and greater sensitivity for detecting mixtures of wild-type and resistant virus.
If ART is deferred, repeat resistance testing should be considered at the time therapy is initiated **(CIII)**. A genotypic assay is generally preferred **(AIII)**.	If ART is deferred, testing should still be performed because of the greater likelihood that transmitted resistance-associated mutations will be detected earlier in the course of HIV infection. Results of resistance testing may be important when treatment is initiated. Repeat testing at the time ART is initiated should be considered because the patient may have acquired a drug-resistant virus (i.e., superinfection).
In ART-naïve patients with chronic HIV infection: Drug-resistance testing is recommended at the time of entry into HIV care, regardless of whether therapy is initiated immediately or deferred **(AIII)**. A genotypic assay is generally preferred **(AIII)**.	Transmitted HIV with baseline resistance to at least one drug is seen in 6%–16% of patients, and suboptimal virologic responses may be seen in patients with baseline resistant mutations. Some drug-resistance mutations can remain detectable for years in untreated chronically infected patients.
If therapy is deferred, repeat resistance testing should be considered prior to the initiation of ART **(CIII)**. A genotypic assay is generally preferred **(AIII)**.	Repeat testing prior to initiation of ART should be considered because the patient may have acquired a drug-resistant virus (i.e., a superinfection). Genotypic testing is preferable to phenotypic testing because of lower cost, faster turnaround time, and greater sensitivity for detecting mixtures of wild-type and resistant virus.
If an INSTI is considered for an ART-naïve patient and transmitted INSTI resistance is a concern, providers may wish to supplement standard resistance testing with a specific INSTI genotypic resistance assay **(CIII)**.	Standard genotypic drug-resistance assays test only for mutations in the RT and PR genes.

Table 4. Recommendations for Using Drug-Resistance Assays
Page 2 of 2

Clinical Setting/Recommendation	Rationale
In patients with virologic failure: Drug-resistance testing is recommended in persons on combination ART with HIV RNA levels >1,000 copies/mL **(AI)**. In persons with HIV RNA levels >500 but <1,000 copies/mL, testing may be unsuccessful but should still be considered **(BII)**.	Testing can help determine the role of resistance in drug failure and maximize the clinician's ability to select active drugs for the new regimen. Drug-resistance testing should be performed while the patient is taking prescribed ARV drugs or, if not possible, within 4 weeks after discontinuing therapy.
A standard genotypic resistance assay is generally preferred for those experiencing virologic failure on their first or second regimens **(AIII)**.	Genotypic testing is preferable to phenotypic testing because of lower cost, faster turnaround time, and greater sensitivity for detecting mixtures of wild-type and resistant virus.
In patients failing INSTI-based regimens, genotypic testing for INSTI resistance should be considered to determine whether to include drugs from this class in subsequent regimens **(BIII)**.	Standard genotypic drug-resistance assays test only for mutations in the RT and PR genes.
Addition of phenotypic assay to genotypic assay is generally preferred for those with known or suspected complex drug-resistance patterns, particularly to PIs **(BIII)**.	Phenotypic testing can provide useful additional information for those with complex drug-resistance mutation patterns, particularly to PIs.
In patients with suboptimal suppression of viral load: Drug-resistance testing is recommended for persons with suboptimal suppression of viral load after initiation of ART **(AII)**.	Testing can help determine the role of resistance and thus assist the clinician in identifying the number of active drugs available for a new regimen.
In HIV-infected pregnant women: Genotypic resistance testing is recommended for all pregnant women prior to initiation of ART **(AIII)** and for those entering pregnancy with detectable HIV RNA levels while on therapy **(AI)**.	The goal of ART in HIV-infected pregnant women is to achieve maximal viral suppression for treatment of maternal HIV infection and for prevention of perinatal transmission of HIV. Genotypic resistance testing will assist the clinician in selecting the optimal regimen for the patient.
Drug-resistance assay not usually recommended	
After therapy discontinued: Drug-resistance testing is not usually recommended after discontinuation (>4 weeks) of ARV drugs **(BIII)**.	Drug-resistance mutations might become minor species in the absence of selective drug pressure, and available assays might not detect minor drug-resistant species. If testing is performed in this setting, the detection of drug resistance may be of value; however, the absence of resistance does not rule out the presence of minor drug-resistant species.
In patients with low HIV RNA levels: Drug-resistance testing is not usually recommended in persons with a plasma viral load <500 copies/mL **(AIII)**.	Resistance assays cannot be consistently performed given low HIV RNA levels.

HLA-B*5701 SCREENING (Updated December 1, 2007)

Panel's Recommendations:

- ***The Panel recommends screening for HLA-B*5701 before starting patients on an abacavir (ABC)-containing regimen to reduce the risk of hypersensitivity reaction (HSR) (AI).***
- ***HLA-B*5701-positive patients should not be prescribed ABC (AI).***
- ***The positive status should be recorded as an ABC allergy in the patient's medical record (AII).***
- ***When HLA-B*5701 screening is not readily available, it remains reasonable to initiate ABC with appropriate clinical counseling and monitoring for any signs of HSR (CIII).***

Rating of Recommendations: A = Strong; B = Moderate; C = Optional
Rating of Evidence: I = data from randomized controlled trials; II = data from well-designed nonrandomized trials or observational cohort studies with long-term clinical outcomes; III = expert opinion

The ABC HSR is a multiorgan clinical syndrome typically seen within the initial 6 weeks of ABC treatment. This reaction has been reported in 5%–8% of patients participating in clinical trials when using clinical criteria for the diagnosis, and it is the major reason for early discontinuation of ABC. Discontinuing ABC usually promptly reverses HSR, whereas subsequent rechallenge can cause a rapid, severe, and even life-threatening recurrence *[1]*.

Studies that evaluated demographic risk factors for ABC HSR have shown racial background as a risk factor, with white patients generally having a higher risk (5%–8%) than black patients (2%–3%). Several groups reported a highly significant association between ABC HSR and the presence of the major histocompatibility complex (MHC) class I allele HLA-B*5701 *[2-3]*. Because the clinical criteria used for ABC HSR are overly sensitive and may lead to false-positive ABC HSR diagnoses, an ABC skin patch test (SPT) was developed as a research tool to immunologically confirm ABC HSR *[4]*. A positive ABC SPT is an ABC-specific delayed HSR that results in redness and swelling at the skin site of application. All ABC SPT–positive patients studied were also positive for the HLA-B*5701 allele *[5]*. The ABC SPT could be falsely negative for some patients with ABC HSR and, at this point, is not recommended for use as a clinical tool. The PREDICT-1 study randomized patients before starting ABC either to be prospectively screened for HLA-B*5701 (with HLA-B*5701–positive patients not offered ABC) or to standard of care at the time of the study (i.e., no HLA screening, with all patients receiving ABC) *[6]*. The overall HLA-B*5701 prevalence in this predominately white population was 5.6%. In this cohort, screening for HLA-B*5701 eliminated immunologic ABC HSR (defined as ABC SPT positive) compared with standard of care (0% vs. 2.7%), yielding a 100% negative predictive value with respect to SPT and significantly decreasing the rate of clinically suspected ABC HSR (3.4% vs. 7.8%). The SHAPE study corroborated the low rate of immunologically validated ABC HSR in black patients and confirmed the utility of HLA-B*5701 screening for the risk of ABC HSR (100% sensitivity in black and white populations) *[7]*.

On the basis of the results of these studies, the Panel recommends screening for HLA-B*5701 before starting patients on an ABC-containing regimen **(AI)**. HLA-B*5701–positive patients should not be prescribed ABC **(AI)**, and the positive status should be recorded as an ABC allergy in the patient's medical record **(AII)**. HLA-B*5701 testing is needed only once in a patient's lifetime; thus, efforts to carefully record and maintain the test result and to educate the patient about its implications are important. The specificity of the HLA-B*5701 test in predicting ABC HSR is lower than the sensitivity (i.e., 33%–50% of HLA-B*5701–positive patients would likely not develop confirmed ABC HSR if exposed to ABC). HLA-B*5701 should not be used as a substitute for clinical judgment or pharmacovigilance, because a negative HLA-B*5701 result does not absolutely rule out the possibility of some form of ABC HSR. When HLA-B*5701 screening is not readily available, it remains reasonable to initiate ABC with appropriate clinical counseling and monitoring for any signs of ABC HSR **(CIII)**.

CORECEPTOR TROPISM ASSAYS (Updated January 10, 2011)

Panel's Recommendations:

- ***Coreceptor tropism assay should be performed whenever the use of a CCR5 inhibitor is being considered (AI).***
- ***Coreceptor tropism testing might also be considered for patients who exhibit virologic failure on a CCR5 inhibitor (CIII).***

Rating of Recommendations: A = Strong; B = Moderate; C = Optional
Rating of Evidence: I = data from randomized controlled trials; II = data from well-designed nonrandomized trials or observational cohort studies with long-term clinical outcomes; III = expert opinion

HIV enters cells by a complex process that involves sequential attachment to the CD4 receptor followed by binding to either the CCR5 or CXCR4 molecules and fusion of the viral and cellular membranes *[1]*. CCR5 inhibitors (i.e., maraviroc [MVC]), prevent HIV entry into target cells by binding to the CCR5 receptor *[2]*. Phenotypic and, to a lesser degree, genotypic assays have been developed that can determine the coreceptor tropism (i.e., CCR5, CXCR4, or both) of the patient's dominant virus population. One assay (*Trofile*, Monogram Biosciences, Inc., South San Francisco, CA) was used to screen patients who were participating in studies that formed the basis of approval for MVC, the only CCR5 inhibitor currently available. Other assays are under development and are currently used primarily for research purposes or in clinical situations in which the *Trofile* assay is not readily available.

Background

The vast majority of patients harbor a CCR5-utilizing virus (R5 virus) during acute/recent infection, which suggests that the R5 variant is preferentially transmitted compared with the CXCR4 (X4) variant. Viruses in many untreated patients eventually exhibit a shift in coreceptor tropism from CCR5 to either CXCR4 or both CCR5 and CXCR4 (i.e., dual- or mixed-tropic; D/M-tropic). This shift is temporally associated with a more rapid decline in CD4 T-cell counts *[3-4]*, although whether this shift is a cause or a consequence of progressive immunodeficiency remains undetermined *[1]*. Antiretroviral (ARV)-treated patients who have extensive drug resistance are more likely to harbor detectable X4- or D/M-tropic variants than untreated patients who have comparable CD4 T-cell counts *[5]*. The prevalence of X4- or D/M-tropic variants increases to more than 50% in treated patients who have CD4 counts <100 cells/mm^3 *[5-6]*.

Phenotypic Assays

There are now at least two high-throughput phenotypic assays that can quantify the coreceptor characteristics of plasma-derived virus. Both involve the generation of laboratory viruses that express patient-derived envelope proteins (i.e., gp120 and gp41). These pseudoviruses are either replication competent (*Phenoscript* assay, VIRalliance, Paris, France) or replication defective (*Trofile* assay, Monogram Biosciences, Inc.) *[7-8]*. These pseudoviruses then are used to infect target cell lines that express either CCR5 or CXCR4. In the *Trofile* assay, the coreceptor tropism of the patient-derived virus is confirmed by testing the susceptibility of the virus to specific CCR5 or CXCR4 inhibitors *in vitro*. The *Trofile* assay takes about 2 weeks to perform and requires a plasma HIV RNA level ≥1,000 copies/mL.

The performance characteristics of these assays have evolved. Most, if not all, patients enrolled in premarketing clinical trials of MVC and other CCR5 inhibitors were screened with an earlier, less sensitive version of the *Trofile* assay *[7]*. This earlier assay failed to routinely detect low levels of CXCR4-utilizing variants. As a consequence, some patients enrolled in these clinical trials harbored low, undetectable levels of CXCR4-utilizing viruses at baseline and exhibited rapid virologic failure after initiation of a CCR5 inhibitor *[9]*. This assay has since been revised and is now able to detect lower levels of CXCR4-utlizing viruses. *In vitro*, the assay can detect CXCR4-utilizing clones with 100% sensitivity when those clones make up 0.3% of the population *[10]*. Although this more sensitive assay has had limited use in prospective clinical trials, it is now the only one that is commercially available. For unclear reasons, a minority of samples cannot be successfully phenotyped with either generation of the *Trofile* assay. In patients with plasma HIV-1 RNA below the limit of detection, coreceptor usage can be determined from proviral DNA obtained from peripheral blood mononuclear cells; however, the clinical utility of this assay remains to be determined *[11]*.

Genotypic Assays

Genotypic determination of HIV-1 coreceptor usage is based on sequencing the V3-coding region of HIV-1 *env*, the principal determinant of coreceptor usage. A variety of algorithms and bioinformatics programs can be used to predict coreceptor usage from the V3 sequence. When compared to the phenotypic assay, genotypic methods show high specificity (~90%) but only modest sensitivity (~50%–70%) for the presence of a CXCR4-utilizing virus. Given these performance characteristics, these assays may not be sufficiently robust to completely rule out the presence of an X4 or D/M variant *[12]*.

Recent studies in which V3 genotyping was performed on samples from patients screening for clinical trials of MVC suggest that genotyping performed as well as phenotyping in predicting the response to MVC *[13-14]*. On the basis of these data, accessibility, and cost, European guidelines currently favor genotypic testing for determining coreceptor usage. An important caveat to these results is that the majority of patients who received MVC were first shown to have R5 virus by a phenotypic assay (*Trofile*). Consequently, the opportunity to assess treatment response to MVC in patients whose virus was considered R5 by genotype but D/M or X4 by phenotype was limited to a relatively small number of patients. It is also important to note that the genotyping approaches used in these studies are not routinely available from clinical laboratories in the United States at this time.

Given the uncertainty regarding the genotypic assays and fewer logistical barriers to obtaining a phenotype in the United States than elsewhere, the Panel recommends that a phenotype be used as the preferred coreceptor tropism screening test in the United States.

Use of Coreceptor Tropism Assays in Clinical Practice

Coreceptor tropism assays should be used whenever the use of a CCR5 inhibitor is being considered **(AI)**. Coreceptor tropism testing might also be considered for patients who exhibit virologic failure on MVC (or any CCR5 inhibitor) **(CIII)**.

Other potential clinical uses for the tropism assay are for prognostic purposes or for assessment of tropism prior to starting antiretroviral therapy (ART), in case a CCR5 inhibitor is required later (e.g., in a regimen change for toxicity). Currently, sufficient data do not exist to support these uses.

Treatment Goals (Updated January 10, 2011)

Eradication of HIV infection cannot be achieved with available antiretroviral (ARV) regimens even when new, potent drugs are added to a regimen already suppressing plasma viral load below the limits of detection with commercially available assays *[1]*. This is chiefly because the pool of latently infected CD4 T-cells is established during the earliest stages of acute HIV infection *[2]* and persists with a long half-life, despite prolonged suppression of plasma viremia *[3-7]*. Therefore the primary goals for initiating antiretroviral therapy (ART) are to:

- reduce HIV-associated morbidity and prolong the duration and quality of survival,
- restore and preserve immunologic function,
- maximally and durably suppress plasma HIV viral load (see **Plasma HIV RNA Testing**), and
- prevent HIV transmission.

Adoption of treatment strategies recommended in these guidelines has reduced HIV-related morbidity and mortality *[8-11]* and has reduced perinatal *[12]* and, probably, behavior-associated transmission of HIV *[13-16]*. HIV suppression with ART may also decrease inflammation and immune activation thought to contribute to higher rates of cardiovascular and other end-organ damage reported in HIV-infected cohorts. (See **Initiating Antiretroviral Therapy**.) Maximal and durable suppression of plasma viremia delays or prevents the selection of drug-resistance mutations, preserves CD4 T-cell numbers, and confers substantial clinical benefits, all of which are important treatment goals *[17-18]*.

Achieving viral suppression requires the use of ARV regimens with at least two, and preferably three, active drugs from two or more drug classes. Baseline resistance testing and patient characteristics should guide the specific regimen design. (See **What to Start: Initial Combination Regimens for the Antiretroviral-Naïve Patient**.) When initial suppression is not achieved or is lost, rapidly changing to a new regimen with at least two active drugs is required. (See **Virologic and Immunologic Failure**.) The increasing number of drugs and drug classes makes viral suppression below detection limits an appropriate goal in all patients, even those with primary or acquired drug resistance.

Viral load reduction to below limits of assay detection in an ART-naïve patient usually occurs within the first 12–24 weeks of therapy. Predictors of virologic success include:

- high potency of ARV regimen,
- excellent adherence to treatment regimen *[19]*,
- low baseline viremia *[20]*,
- higher baseline CD4 count (>200 cells/mm^3) *[21]*, and
- rapid reduction of viremia in response to treatment *[20, 22]*.

Successful outcomes are usually observed although adherence difficulties may lower the success rate in clinical practice to below the 90% rate commonly seen in clinical trials *[23]*.

STRATEGIES TO ACHIEVE TREATMENT GOALS

Achieving treatment goals requires a balance of sometimes competing considerations, outlined below. Providers and patients must work together to define individualized strategies to achieve treatment goals.

Selection of Initial Combination Regimen

Several preferred and alternative ARV regimens are recommended for use. (See **What to Start**.) Many of these regimens have comparable efficacy but vary to some degree in dosing frequency and symmetry, pill burden, drug interactions, and potential side effects. A regimen should be tailored to each patient to enhance adherence and thus improve long-term treatment success. Individual regimen choice is based on such considerations as expected side

effects, convenience, comorbidities, interactions with concomitant medications, and results of pretreatment genotypic drug-resistance testing.

Pretreatment Drug-Resistance Testing

Current studies suggest a 6%–16% prevalence of HIV drug resistance in ART-naïve patients *[24-28]*, and some studies suggest that the presence of transmitted drug-resistant viruses may lead to suboptimal virologic responses *[29]*. Therefore, pretreatment genotypic resistance testing should be used to guide selection of the most optimal initial ARV regimen. (See **Drug-Resistance Testing**.)

Improving Adherence

Suboptimal adherence may result in reduced treatment response. Incomplete adherence can result from complex medication regimens; patient factors, such as active substance abuse and depression; and health system issues, including interruptions in access to medication and inadequate treatment education and support. Conditions that promote adherence should be maximized prior to and after initiation of ART. (See **Adherence to Antiretroviral Therapy**.)

Initiating Antiretroviral Therapy in Treatment-Naïve Patients (Updated January 10, 2011)

Panel's Recommendations:

- ***Antiretroviral therapy (ART) should be initiated in all patients with a history of an AIDS-defining illness or with a CD4 count <350 cells/mm^3 (AI).***
- ***ART is also recommended for patients with CD4 counts between 350 and 500 cells/mm^3 (A/B*-II).***
- ***ART should be initiated, regardless of CD4 count, in patients with the following conditions: HIV-associated nephropathy (HIVAN) (AII) and hepatitis B virus (HBV) coinfection when treatment of HBV is indicated (AIII).***
- ***A combination antiretroviral (ARV) drug regimen is also recommended for pregnant women who do not meet criteria for treatment with the goal to prevent perinatal transmission (AI).***
- ***For patients with CD4 counts >500 cells/mm^3, Panel members are evenly divided: 50% favor starting ART at this stage of HIV disease (B); 50% view initiating therapy at this stage as optional (C) (B/C-III).***
- ***Patients initiating ART should be willing and able to commit to lifelong treatment and should understand the benefits and risks of therapy and the importance of adherence (AIII). Patients may choose to postpone therapy, and providers, on a case-by-case basis, may elect to defer therapy based on clinical and/or psychosocial factors.***

Rating of Recommendations: A = Strong; B = Moderate; C = Optional
Rating of Evidence: I = data from randomized controlled trials; II = data from well-designed nonrandomized trials or observational cohort studies with long-term clinical outcomes; III = expert opinion

* ***Panel members are divided on the strength of this recommendation: 55% voted for strong recommendation (A) and 45% voted for moderate recommendation (B).***

The primary goal of ART is to reduce HIV-associated morbidity and mortality. This is best accomplished by using ART to maximally inhibit HIV replication, as measured by consistent plasma HIV RNA (viral load) values below the level of detection using commercially available assays. Additional benefits of ART, supported by accumulating evidence, are reduction in HIV-associated inflammation and its associated complications and reduction in HIV transmission.

Over the past 20 years, the Panel has made several changes to the recommendations on when to start therapy based on prevailing clinical trial and cohort data and therapeutic options available at the time of each revision. The standard procedure for the Panel is to only make recommendations in agreement with two-thirds of the Panel members. This has not been possible for the ***When to Start*** recommendations in this version of the guidelines. Accordingly, the breakdown of votes is presented for recommendations supported by less than two-thirds of Panel members.

Randomized controlled trials provide evidence supporting the benefit of ART in patients with CD4 counts ≤350 cells/mm^3. However, such evidence showing benefit for patients with higher CD4 cell counts is not yet available. Based on cumulative observational cohort data demonstrating benefits of ART in reducing AIDS- and non-AIDS-associated morbidity and mortality, the Panel now recommends ART for patients with CD4 count between 350 and 500 cells/mm^3 **(A-B/II)**. For patients with CD4 count >500 cells/mm^3, Panel members are evenly divided: 50% favor starting ART at earlier stages of HIV disease **(BIII)**; 50% view initiating therapy at this stage as optional **(CIII)**.

Panel members favoring earlier initiation of therapy base their recommendation on several recent developments: (1) report from at least one recent cohort study demonstrating survival benefit with initiation of ART at CD4 count >500 cells/mm^3; (2) growing awareness that untreated HIV infection may be associated with development of many non-AIDS-defining diseases, including cardiovascular disease, kidney disease, liver disease, and malignancy; (3) availability of ARV regimens that are more effective, more convenient, and better tolerated than ARV combinations no longer in use; and (4) increasing evidence that effective ART reduces HIV transmission **(BIII)**.

The other 50% of the Panel members feel that current evidence does not definitively demonstrate clear benefit of ART in all patients with CD4 count >500 cells/mm^3. They also feel that risks of short- or long-term drug-related complications, nonadherence to lifelong therapy in asymptomatic patients, and potential for development of drug resistance may offset possible benefits of earlier initiation of therapy. Thus, pending more definitive supporting evidence, these Panel members recommend that therapy in this setting should be optional and considered on a case-by-case basis **(CIII)**.

The known benefits, risks, and limitations of ART, as well as the strength of the recommendations according to CD4 count levels, are discussed below.

BENEFITS OF ANTIRETROVIRAL THERAPY

Earlier studies definitively showed that potent combination ART improves survival and reduces AIDS-related complications in patients with advanced HIV disease. There is now increasing evidence demonstrating the benefits of viral suppression and immunologic responses on reducing mortality and non-AIDS-related complications in patients with higher pretreatment CD4 counts. The following is a focused discussion of the rationale that forms the basis for the Panel's recommendation favoring earlier treatment.

Reduction in Mortality and/or AIDS-Related Morbidity

Patients with a history of an AIDS-defining illness or CD4 count <350 cells/mm^3

HIV-infected patients with CD4 counts <200 cells/mm^3 are at higher risk of opportunistic diseases, non-AIDS morbidity, and death. Randomized controlled trials in patients with CD4 counts <200 cells/mm^3 and/or a history of an AIDS-defining condition provide strong evidence that ART improves survival and delays disease progression in these patients *[1-3]*. Long-term data from multiple observational cohort studies evaluating earlier ART (>200 cells/mm^3) compared with later treatment (<200 cells/mm^3) have also provided strong support for these findings *[4-8]*.

Few large, randomized controlled trials address when to start therapy in patients with CD4 counts >200 cells/mm^3. CIPRA HT-001 is a randomized clinical trial conducted in Haiti. Study participants were randomized to start ART at CD4 counts of 200–350 cells/mm^3 or to defer treatment until their CD4 counts dropped below 200 cells/mm^3 or they developed an AIDS-defining condition. In an interim analysis of the study, a higher mortality rate (hazard ratio [HR] = 4.0, p = 0.0011) and greater incident tuberculosis (HR = 2.0, p = 0.0125) were observed among patients who deferred therapy compared with participants who began ART with CD4 counts of 200–350 cells/mm^3 *[9]*. This evidence led to the study Data Safety Monitoring Board's recommendation to terminate the trial before completion.

The SMART study was a multinational trial enrolling more than 5,400 participants with CD4 counts >350 cells/mm^3. Participants were randomized to continuous ART or to treatment interruption until CD4 count dropped to <250 cells/mm^3. In a subgroup analysis involving the 249 study participants who were ART naïve at enrollment, a trend of lower risk of serious AIDS- and non-AIDS-related events was seen in those who initiated therapy immediately compared with those who deferred therapy until CD4 count dropped to <250 cells/mm^3 (p = 0.06) *[10]*.

Collectively, these studies support the Panel's recommendation that ART should be initiated in patients with a history of an AIDS-defining illness or with a CD4 count <350 cells/mm^3 **(AI)**.

Patients with a CD4 count between 350 and 500 cells/mm^3

There are no randomized trials using current combination regimens in patients with CD4 counts >350 cells/mm^3 to provide data that directly address the question of when to start therapy in patients with CD4 counts of 350–500 cells/mm^3. Data from the ART Cohort Collaboration (ART-CC), which included 61,798 patient-years of follow-up, showed a declining risk of AIDS or death for up to 5 years in subjects starting therapy with a CD4 count ≥350 cells/mm^3 compared with subjects starting between 200 and 349 cells/mm^3 *[11]*. A more recent rigorous analysis of this cohort found that deferring therapy until the 251 to 350 cells/mm^3 range was associated with a higher rate of

progression to AIDS and death compared with initiating therapy in the 351 to 450 cells/mm^3 range (risk ratio: 1.28, 95% confidence interval [CI]: 1.04 to 1.57) *[6]*.

In a collaboration of North American cohort studies (NA-ACCORD) that evaluated patients regardless of whether they had started therapy, the 6,278 patients who deferred therapy until CD4 counts were <350 cells/mm^3 had an increased risk of death compared with 2,084 patients who initiated therapy with CD4 counts between 351 and 500 cells/mm^3 (risk ratio: 1.69, 95% CI: 1.26 to 2.26) after adjustment for other factors that differed between these two groups *[12]*.

When interpreting both of these cohort studies it is important to note that although the relative risk of a mortality event is evident, the overall number of events was small. In these cohort studies, the relative risks determined could have been influenced by unmeasured confounders that cannot be adjusted for in the analysis. The findings from these observational cohort studies point to potential harm if therapy is deferred until CD4 count falls to <350 cells/mm^3. Based on these findings, combined with emerging biologic evidence regarding potential damage to end organs from inflammation associated with untreated HIV replication and the potential reduction in HIV transmission with treatment (see below), the Panel recommends initiation of ART in patients with CD4 counts between 350 and 500 cells/mm^3. Panel members are divided on the strength of this recommendation: 55% voted for strong recommendation (A) and 45% voted for moderate recommendation (B) **(A/B-II)**.

Patients with a CD4 count >500 cells/mm^3

The NA-ACCORD study also observed patients who started treatment at CD4 counts >500 cells/mm^3 or after CD4 counts dropped below this threshold. The adjusted mortality rates were significantly higher among the 6,935 patients who deferred therapy until CD4 count fell to <500 cells/mm^3 compared with rates in the 2,200 patients who started therapy while CD4 count was > 500 cells/mm^3 (risk ratio: 1.94, 95% CI: 1.37 to 2.79) *[12]*. Although large and generally representative of care in the United States, the study has several limitations, including the small number of deaths and the potential for unmeasured confounders that might have influenced outcomes independent of ART.

In contrast, analysis of the ART-CC cohort failed to identify a benefit for patients initiating ART with CD4 counts > 450 cells/mm^3. This analysis also did not identify a harmful effect of this strategy *[6]*. Deferral of therapy to the 351–450 cells/mm^3 range was associated with a similar rate of progression to AIDS/death compared with initiation of therapy in the 451–550 cells/mm^3 range (risk ratio: 0.99, 95% CI: 0.76 to 1.29). This study also found that the proportion of patients with CD4 counts between 451 and 550 cells/mm^3 who would progress to AIDS or death before having a CD4 count <450 cells/mm^3 was low (1.6%; 95% CI: 1.1 to 2.1%).

Based on these data, along with a better understanding of the pathogenesis of HIV infection and the growing awareness that untreated HIV infection increases the risk of many non-AIDS-defining diseases (see below), 50% of Panel members favor initiation of ART in HIV-infected persons with a CD4 count >500 cells/mm^3 **(BIII)**.

The other 50% of the Panel members are reluctant to broadly recommend starting ART at higher CD4 cell counts and consider that therapy should be optional at this stage of HIV disease **(CIII)**. In making this recommendation, the Panel members note that the amount of data supporting initiation of therapy decreases as the CD4 count increases above 350–500 cells/mm^3, and that concerns remain over the unknown overall benefit and long-term risks with earlier treatment.

When discussing starting ART at higher CD4 cell counts (>500 cells/mm^3), clinicians should inform patients that data on the clinical benefit of starting treatment at such levels is not conclusive. There is a need for further ongoing research (both with randomized clinical trials and cohort studies) to assess the short- and long-term clinical and public health benefits and cost effectiveness of starting therapy at higher CD4 counts. Such research findings will provide guidance for future recommendations by the Panel.

Effects of Antiretroviral Therapy on HIV-Related Morbidity

HIV-related morbidity and mortality derive not only from immune deficiency but also from direct effects of HIV on specific end organs and the indirect effects of HIV-associated inflammation on these organs. In general, the available data demonstrate that:

- Untreated HIV infection may have detrimental effects at all stages of infection.
- Treatment is beneficial even when initiated later in infection. However, later therapy may not repair damage associated with viral replication during early stages of infection.
- Earlier treatment may prevent the damage associated with HIV replication during early stages of infection.

Clinical studies have demonstrated that sustaining viral suppression and maintaining higher CD4 count, mostly as a result of effective combination ART, delay or prevent some non-AIDS-defining complications, such as HIV-associated kidney disease. Sustained viral suppression and immune recovery may also delay or prevent other disorders, such as liver disease, cardiovascular disease, and malignancies, as discussed below.

HIV-associated nephropathy (HIVAN)

HIVAN is the most common cause of chronic kidney disease in HIV-infected individuals that may lead to end-stage kidney disease *[13]*. HIVAN is seen almost exclusively in black patients and can occur at any CD4 count. Ongoing viral replication appears to be directly involved in renal injury *[14]*. HIVAN is extremely uncommon in virologically suppressed patients *[15]*. ART in patients with HIVAN has been associated with both preserved renal function and prolonged survival *[16-18]* and therefore should be started in these patients **(AII)**.

Coinfection with hepatitis B virus (HBV) and/or hepatitis C virus (HCV)

HIV infection is associated with more rapid progression of viral hepatitis-related liver disease, including cirrhosis, end-stage liver disease, hepatocellular carcinoma, and fatal hepatic failure *[19-20]*. Although the mechanisms of accelerated liver disease in HIV-infected patients have not been fully elucidated, HIV-related immunodeficiency and a direct interaction of HIV with hepatic stellate and Kupffer cells have been implicated *[21-24]*. ART may attenuate liver disease progression in persons coinfected with HBV and/or HCV by preserving or restoring immune function and reducing HIV-related immune activation and inflammation *[25-27]*. ARV drugs active against both HIV and HBV (e.g., tenofovir disoproxil fumarate [TDF], lamivudine [3TC], emtricitabine [FTC]) may also prevent the development of significant liver disease by directly suppressing HBV replication *[28-29]*. Although ARV drugs do not directly inhibit HCV replication, HCV treatment outcomes may be improved if HIV replication is controlled or if CD4 counts are increased *[30]*. The presence of chronic viral hepatitis increases the risk of ARV-induced liver injury; however, the majority of coinfected persons do not develop clinically significant liver injury, particularly those receiving recommended ARV regimens *[31-33]*. Some studies suggest that the rate of hepatotoxicity is greater in persons with more advanced HIV disease. Nevirapine (NVP) toxicity is a notable exception: the hypersensitivity reaction and associated hepatotoxicity to this drug are more frequent in patients with higher CD4 cell counts *[34]*. Collectively, these data suggest earlier treatment of HIV infection in persons coinfected with HBV, and possibly HCV **(CIII)**, may reduce the risk of liver disease progression. Furthermore, ART including drugs active against both HIV and HBV should be started in all patients coinfected with HBV who are also going to receive HBV treatment **(AIII)**.

Cardiovascular disease

Cardiovascular disease is a major cause of mortality among HIV-infected patients, accounting for a third of serious non-AIDS conditions and at least 10% of deaths among HIV-infected patients *[35-36]*. Studies link exposure to specific ARV drugs to a higher risk of cardiovascular disease *[37-38]*. Certain HIV treatment regimens are associated with a more atherogenic lipid profile as assessed by lipoprotein particle size analysis among HIV-infected men compared with uninfected controls *[39]*. Untreated HIV infection may also be associated with an increased risk of cardiovascular disease. In some cross-sectional studies, patients with HIV have higher levels of markers of inflammation and endothelial dysfunction than HIV-uninfected controls *[40-42]*. In two randomized trials, markers of inflammation and coagulation increased following treatment interruption *[43-44]*. One study suggests that ART may improve endothelial function *[45]*.

In the SMART study, the risk of cardiovascular events was greater in participants randomized to CD4-guided treatment interruption compared with participants who received continuous ART *[46]*. In other studies, ART resulted in marked improvement in parameters associated with cardiovascular diseases, including markers of inflammation (e.g., interleukin 6 [IL-6] and high sensitivity C-reactive protein [hsCRP]) and endothelial dysfunction *[41, 45]*. There is also a modest association between lower CD4 count while on therapy and short-term risk of cardiovascular disease

[42, 47-48]. However, in at least one of these cohorts (the CASCADE study), the link between CD4 count and fatal cardiovascular events was no longer statistically significant when adjusting for plasma HIV RNA level. Collectively, the data linking viremia and endothelial dysfunction and inflammation, the increased risk of cardiovascular events with treatment interruption, and the association between cardiovascular disease and CD4 cell depletion suggest that early control of HIV replication with ART can be used as a strategy to reduce cardiovascular disease risk **(BIII)**.

Malignancies

Several population-based analyses suggest increased incidence of non-AIDS-associated malignancies during chronic HIV infection. The incidence of non-AIDS malignancy in HIV-infected subjects is higher than in matched HIV-uninfected controls *[49]*. Large cohort studies of mostly patients receiving ART have reported a consistent link between low CD4 counts (<350–500 cells/mm^3) and the risk of AIDS- and/or non-AIDS-defining malignancy *[42, 47, 50-53]*. The ANRS C04 Study demonstrated a statistically significant relative risk of all cancers evaluated (except for anal carcinoma) in patients with CD4 counts <500 cells/mm^3 compared with patients with current CD4 counts >500 cells/mm^3 and a protective effect of ART for HIV-associated malignancies *[50]*. This potential effect of HIV-associated immunodeficiency is particularly striking with regard to cancers associated with chronic viral infections (e.g., HBV, HCV, human papilloma virus [HPV], Epstein-Barr virus [EBV], human herpes virus-8 [HHV-8]) *[54-55]*. Cumulative HIV viremia itself may also be associated with the risk of non-Hodgkin lymphoma and other AIDS-defining malignancies, independent of other factors *[53, 56]*. Together this evidence suggests that initiating ART to suppress HIV replication and maintain CD4 counts at above 350–500 cells/mm^3 may reduce the risk of both AIDS-defining and non-AIDS-defining malignancies **(CIII)**.

Neurocognitive decline

Early in the HIV epidemic, HIV was identified in brain tissue *[57]* and assumed to be the cause of AIDS dementia complex *[58]*. The improvement of AIDS dementia complex symptoms with the use of ART supported this assumption *[59-60]*. The CASCADE observational cohort reported a dramatic decline in the incidence of HIV-associated dementia from 6.49 per 1,000 person-years (before 1997) to 0.66 per 1,000 person-years (2003–2006), after the widespread use of potent ART *[61]*. In this cohort, having a current CD4 count >350 cells/mm^3 was associated with the lowest risk of developing HIV-associated dementia. HIV infection has also been associated with a number of less severe neurologic complications, including changes in neuropsychological ability, speed of processing, and everyday functioning *[62]*. Such syndromes also were predicted by a lower pretherapy CD4 nadir and/or by CD4 count while on therapy *[63-64]*. Additional clinical data are needed to determine the relative roles of ongoing HIV replication and potential neurotoxicity of ARV agents in the development of neurocognitive dysfunction. Whether early initiation of therapy will prevent HIV-associated neurocognitive dysfunction remains unclear. However, the neurological complications that may accompany uncontrolled HIV replication and CD4 depletion suggest a potential benefit of earlier initiation of ART **(CIII)**.

Age and treatment-related immune reconstitution

The CD4 cell response to ART is an important predictor of short-term and long-term morbidity and mortality. Treatment initiation at an older age is consistently associated with a less robust CD4 count response; starting therapy at a younger age may result in better immunologic and perhaps clinical outcomes *[65-67]***(CIII)**.

T-cell activation and inflammation

Early untreated HIV infection is associated with sustained high-level inflammation and T-cell activation *[68-70]*. The degree of T-cell activation during untreated HIV disease is associated with risk of subsequent disease progression, independent of other factors such as plasma HIV RNA levels and the peripheral CD4 T-cell count *[71-72]*. ART results in a rapid, but often incomplete, decrease in most markers of HIV-associated immune activation *[73-77]*. Persistent T-cell activation and/or T-cell dysfunction is particularly evident among patients who delay therapy until later stage disease (CD4 count <350 cells/mm^3) *[74, 77-78]*. The degree of persistent inflammation during treatment, as represented by the levels of IL-6, may be independently associated with risk of death *[44]*. Collectively, these observations support earlier use of ART for at least two reasons. First, treatment decreases the level of inflammation and T-cell activation, which may be associated with reduced short-term risk of AIDS- and non-AIDS-related

morbidity and mortality *[44, 79-80]*. Second, because the degree of residual inflammation and/or T-cell dysfunction during ART appears to be higher in patients with lower CD4 cell nadirs *[74, 77-78]*, earlier treatment may result in less residual immunological perturbations on therapy, and hence less risk for AIDS- and non-AIDS-related complications **(CIII)**.

Prevention of HIV Transmission

Prevention of mother-to-child transmission

Effective ART reduces transmission of HIV. The most dramatic and well-established example of this effect is the use of ART in pregnant women to prevent mother-to-child transmission (MTCT) of HIV. Effective suppression of HIV replication, as reflected in plasma HIV RNA, is a key determinant in reducing perinatal transmission. In the United States, the use of combination ART during pregnancy has reduced the HIV transmission rate from approximately 20%–30% to <2% *[81]*. Thus, use of combination ARV drug regimens is recommended for all HIV-infected pregnant women to prevent MTCT of HIV **(AI)**, even if the mother does not meet the criteria for initiation of therapy for treatment of her HIV infection. Following delivery, considerations regarding continuation of the ARV regimen for maternal therapeutic indications are the same as for other nonpregnant individuals. For detailed recommendations, see ***Perinatal Guidelines*** *[82]*.

Prevention of sexual transmission

Emerging evidence supports the concept of "treatment as prevention" of sexual transmission of HIV. Lower plasma HIV RNA levels are associated with decreases in the concentration of the virus in genital secretions *[83-84]*. Studies of HIV serodiscordant heterosexual couples have demonstrated a relationship between the level of plasma viremia and HIV transmission risk: when plasma HIV RNA levels are lower, transmission events are less common *[85-89]*. These investigations, as well as other observational studies and modeling analyses demonstrating a decreased rate of HIV transmission among serodiscordant heterosexual couples following the introduction of ART, suggest that suppression of viremia in ART-adherent patients with no concomitant sexually transmitted infections (STIs) substantially reduces the risk of HIV transmission *[88-93]*. Based on these studies, the use of effective ART regardless of CD4 count is likely to reduce transmission to the uninfected sexual partner **(BII)**.

POTENTIAL LIMITATIONS OF EARLIER INITIATION OF THERAPY

Although there are benefits associated with earlier initiation of ART, there are also potential limitations to this approach. Concerns about long-term toxicity and the development of ARV resistance have served as a rationale for the deferral of HIV therapy. Earlier initiation of ART at higher CD4 counts (e.g., >500 cells/mm^3) results in greater cumulative time on therapy. Assuming treatment for many decades after initiation, the additional therapy represents a small percentage of the total time on ART for most patients.

Although newer ARV regimens are generally better tolerated, more convenient, and more potent than older regimens, there are fewer longer term safety data for the newer agents. Analyses supporting ART initiation at CD4 counts >350 cells/mm^3 (e.g., NA-ACCORD and ART-CC) were conducted with cohorts largely treated with regimens less commonly used in clinical practice. These studies reported on clinical endpoints of death and/or AIDS disease progression but lacked information on drug toxicities, resistance, or adherence. Therefore, in considering earlier initiation of therapy, concerns for some adverse consequences of ART remain.

Antiretroviral Drug Toxicities and Quality of Life

Earlier initiation of ART extends exposure to ARV agents by several years. The D:A:D study found an increased incidence of cardiovascular disease associated with cumulative exposure to some drugs within the nucleoside reverse transcriptase inhibitor (NRTI) and protease inhibitor (PI) classes *[38, 94]*. In the SMART study, continuous exposure to ART has been associated with significantly greater loss of bone density compared with interruption or deferral of therapy *[46]*. There may be unknown complications related to cumulative use of ARV drugs for many decades. A list of known ARV-associated toxicities can be found in **Adverse Effects of Antiretroviral Agents**.

Although ART frequently improves quality of life among symptomatic patients, it may also be associated with reduced quality of life in some patients, especially those who are asymptomatic at initiation of therapy. Although better tolerated and easier to administer than older drugs, most ARV drugs now used in first-line regimens can cause side effects that may reduce quality of life. Efavirenz (EFV), for example, can cause neurocognitive or psychiatric side effects, and all the PIs have been associated with gastrointestinal side effects. Furthermore, some patients may find that the inconvenience of taking medication every day outweighs the overall benefit and might choose to delay therapy whenever possible.

Drug Resistance

Very early treatment initiation may lead to an earlier onset of drug resistance selection in nonadherent patients. The consequent harm is loss of important drugs or drug classes and risk of transmission of drug-resistant HIV. Some asymptomatic patients may be less motivated to remain adherent to their HIV treatment regimens if treatment is initiated far in advance of an immediate risk of HIV-associated morbidity and mortality. The greater convenience and potency of current ARV regimens facilitate adherence and reduce the risk of ARV resistance. One study suggests that the risk of drug resistance at the time of virologic failure is lower among patients who initiated treatment at higher CD4 counts *[95]*. Treatment adherence is key to viral suppression and should be stressed prior to initiation of therapy and during follow-up visits.

Nonadherence to Antiretroviral Therapy

At any CD4 count, adherence to therapy is essential to achieve viral suppression and prevent emergence of resistance mutations. Several behavioral and social factors associated with poor adherence, such as untreated major psychiatric disorders, active substance abuse, social circumstances, patient concerns about side effects, and poor adherence to clinic visits, have been identified. Clinicians should identify areas where additional intervention is needed to improve adherence both before and after initiation of therapy. Some strategies to improve adherence are discussed in **Adherence.**

Cost

Although ART adds to the annual cost of treatment, several modeling studies support the cost effectiveness of HIV therapy initiated soon after diagnosis *[96-98]*. Studies have reported that the annual cost of care is 2½ times higher for patients with CD4 counts <50 cells/mm^3 compared with patients with CD4 counts >350 cells/mm^3 *[99]*. A large proportion of the health care expenditure in patients with advanced infection is from non-ARV drugs and hospitalization. However, no cost comparisons have been reported between those starting ART with a CD4 count between 350 and 500 cells/mm^3 versus >500 cells/ mm^3.

SUMMARY

In earlier versions of these treatment guidelines, concerns about long-term toxicity, reduced quality of life, and the potential for drug resistance served as key reasons to defer HIV therapy for as long as possible. Inherent in this argument was the assumption that the harm associated with viral replication was less than the harm associated with the toxicities of ARV drugs in patients with higher CD4 counts. There is now more evidence that untreated HIV infection has negative consequences on health at all stages of disease. Also, the drug combinations now available are better tolerated than previous regimens, leading to greater efficacy and improved adherence *[100]*. The current guidelines therefore emphasize avoiding adverse consequences of untreated HIV infection while managing potential drug toxicity.

RECOMMENDATIONS

Based on the cumulative weight of evidence described above, the Panel recommends that:

- ART should be initiated in all patients with a history of an AIDS-defining illness or with a CD4 count of <350 cells/mm^3 **(AI)**.
- ART is also recommended for patients with CD4 counts between 350 and 500 cells/mm^3 **(A/B-II)**.*
- ART should also be initiated, regardless of CD4 count, in patients with the following conditions: HIVAN **(AII)** and HBV coinfection when treatment of HBV is indicated **(AIII)**.
- A combination ARV drug regimen is also recommended for pregnant women who do not meet criteria for treatment with the goal to prevent perinatal transmission **(AI)**.
- For patients with CD4 counts >500 cells/mm^3, 50% of the Panel members favor starting ART (B); the other 50% of members view treatment as optional (C) in this setting **(B/C-III)**.
- Patients initiating ART should be willing and able to commit to lifelong treatment and should understand the benefits and risks of therapy and the importance of adherence (**AIII**).
- Patients may choose to postpone therapy, and providers, on a case-by-case basis, may elect to defer therapy based on clinical and/or psychosocial factors.

* The Panel is divided on the strength of this recommendation: 55% of Panel members voted for strong recommendation **(A)** and 45% voted for moderate recommendation **(B)**.

Conditions Favoring More Rapid Initiation of Therapy

Deferring ART may be appropriate in some cases. However, several conditions increase the urgency for therapy, including:

- Pregnancy **(AI)** (Clinicians should refer to the ***Perinatal Guidelines*** for more detailed recommendations for the management of HIV-infected pregnant women.) *[82]*
- AIDS-defining conditions **(AI)**
- Acute opportunistic infections (see discussion below)
- Lower CD4 counts (e.g., <200 cells/mm^3) **(AI)**
- Rapidly declining CD4 counts (e.g., >100 cells/mm^3 decrease per year) **(AIII)**
- Higher viral loads (e.g., >100,000 copies/mL) **(BII)**
- HIVAN **(AII)**
- HBV coinfection when treatment for HBV is indicated **(AIII)**

Acute opportunistic infections

In patients with opportunistic conditions for which there is no effective therapy (e.g., cryptosporidiosis, microsporidiosis, progressive multifocal leukoencephalopathy) but for which ART may improve outcomes by improving immune responses, the benefits of ART outweigh any increased risk, and therefore treatment should be started as soon as possible **(AIII)**.

In the setting of opportunistic infections, such as cryptococcal meningitis or non-tuberculous mycobacterial infections, for which immediate therapy may increase the risk of immune reconstitution inflammatory syndrome (IRIS), a short delay may be warranted before initiating ART *[101-102]* **(CIII)**.

In the setting of other opportunistic infections, such as *Pneumocystis jiroveci* pneumonia (PCP), early initiation of ART is associated with increased survival, and therapy should not be delayed *[3]* **(AI)**.

In patients who have active tuberculosis, initiating ART within the first 1–2 months of treatment for tuberculosis appears to confer a significant survival advantage *[103-104]*. (See ***Mycobacterium Tuberculosis* Disease with HIV Coinfection**.)

Clinicians should refer to the ***Guidelines for Prevention and Treatment of Opportunistic Infections in HIV-Infected Adults and Adolescents*** *[105]* for more detailed discussion on when to initiate ART in the setting of a specific opportunistic infection.

Conditions Where Deferral of Therapy Might be Considered

Some patients and their clinicians may decide to defer therapy for a period of time based on clinical or personal circumstances. The degree to which these factors might argue for deferral of therapy depends on the CD4 count and viral load. Although deferring therapy for the reasons discussed below may be reasonable for patients with high CD4 counts (e.g., >500 cells/mm^3), deferral for patients with much lower CD4 counts (e.g., <200 cells/mm^3) should be considered only in rare situations and should be undertaken with close clinical follow-up. A brief delay in initiating therapy may be considered to allow a patient more time to prepare for lifelong treatment.

When there are significant barriers to adherence

Deferring treatment for patients with higher CD4 counts who are at risk of poor adherence may be prudent while the barriers to adherence are being addressed. However, increased urgency for ART (see above) may override potential predictors of poor adherence.

Several methodologies exist to help providers assess adherence. When the most feasible measure of adherence is self-report, this assessment should be completed at each clinic visit, using one of the available reliable and valid instruments *[106-107]*. If other objective measures are available (e.g., pharmacy refill data, pill count), these methods should also be implemented as therapy begins *[108-110]*. Continuous assessment and counseling make it possible for the clinician to intervene early to address barriers to adherence occurring at any point during treatment.

Presence of comorbidities that complicate or prohibit antiretroviral therapy

Deferral of ART may be considered when either the treatment or manifestations of other medical conditions could complicate the treatment of HIV infection or vice versa. Examples include:

- Patients requiring surgery that might result in an extended interruption of ART.
- Patients taking medications that have clinically significant drug interactions with ART and for whom alternative therapy is not available.

In each of these cases, it is assumed that the situation is temporary and that ART will be initiated after the conflicting condition has resolved.

There are some less common situations in which ART may not be indicated at any time while CD4 counts remain high. In particular, such situations include patients with a poor prognosis due to a concomitant medical condition who would not be expected to gain survival or quality-of-life benefits from ART. Examples include patients with incurable non-HIV-related malignancies or end-stage liver disease who are not being considered for liver transplantation. The decision to forego ART in such patients may be easier in those with higher CD4 counts; they are likely asymptomatic for HIV, and their survival is unlikely to be prolonged by ART. However, it should be noted that ART may improve outcomes, including survival, in patients with some HIV-associated malignancies (e.g., lymphoma or Kaposi's sarcoma) and in patients with liver disease due to chronic HBV or HCV.

Elite HIV controllers or long-term nonprogressors

A small subset of ARV-untreated HIV-infected persons (~3%–5%) are able to maintain normal CD4 cell counts for many years (long-term nonprogressors), while an even smaller subset (~1%) are able to maintain suppressed viral loads for years (elite controllers). It is possible that such patients would not benefit from ART. However, some nonprogressors have high viral loads, and some elite controllers progress clinically or immunologically *[111-112]*. Although therapy may be theoretically beneficial for patients in either group, clinical data supporting therapy for nonprogressors and elite controllers are lacking.

THE NEED FOR EARLY DIAGNOSIS OF HIV

Fundamental to the earlier initiation of therapy recommended in these guidelines is the assumption that patients will be diagnosed early in the course of HIV infection, making earlier initiation of therapy an option. Unfortunately, most HIV-infected patients are not diagnosed until they are at much later stages of disease *[113-116]*. Despite the 2006 Centers for Disease Control and Prevention (CDC) recommendations for routine, opt-out HIV screening in the health care setting *[117]* regardless of perceived risk of infection, the median CD4 count for newly diagnosed patients remains in the ~200 cells/mm^3 range. (The exception is pregnant women diagnosed during prenatal care, who have a much higher median initial CD4 count.) Delay in HIV diagnosis is more often seen in nonwhites, injection drug users, and older patients; a substantial proportion of these individuals develop AIDS-defining illnesses within 1 year of diagnosis *[113-116]*. Therefore, for the current treatment guidelines to have maximum impact, routine HIV screening per current CDC recommendations is essential. It is critical that all newly diagnosed patients be educated about HIV disease and linked to care for full evaluation, follow-up, and management. Once in care, focused effort is required to retain patients in the health care system.

CONCLUSION

The current recommendations are based on increasing evidence that supports earlier initiation of ART than was advocated in previous guidelines. The strength of the recommendations varies with the quality and availability of existing evidence. Panel members are divided regarding the strength of recommendations for starting therapy in patients with higher CD4 cell counts, as discussed above. The Panel will continue to monitor and assess the results of ongoing and planned randomized clinical trials and observational studies, which will provide the Panel with additional guidance to form future recommendations.

What to Start: Initial Combination Regimens for the Antiretroviral-Naïve Patient (Updated January 10, 2011)

Panel's Recommendations:

- ***The Panel recommends the following as preferred regimens for antiretroviral (ARV)-naïve patients:***
  - ***efavirenz/tenofovir/emtricitabine (EFV/TDF/FTC) (AI)***
  - ***ritonavir-boosted atazanavir + tenofovir/emtricitabine (ATV/r + TDF/FTC) (AI)***
  - ***ritonavir-boosted darunavir + tenofovir/emtricitabine (DRV/r + TDF/FTC) (AI)***
  - ***raltegravir + tenofovir/emtricitabine (RAL + TDF/FTC) (AI)***
- ***A list of Panel-recommended alternative and acceptable regimens can be found in Table 5a and Table 5b.***
- ***Selection of a regimen should be individualized based on virologic efficacy, toxicity, pill burden, dosing frequency, drug-drug interaction potential, resistance-testing results, and comorbid conditions.***
- ***Based on individual patient characteristics and needs, in some instances, an alternative regimen may actually be a preferred regimen for a patient.***

Rating of Recommendations: A = Strong; B = Moderate; C = Optional
Rating of Evidence: I = data from randomized controlled trials; II = data from well-designed nonrandomized trials or observational cohort studies with long-term clinical outcomes; III = expert opinion

There are more than 20 approved ARV drugs in 6 mechanistic classes with which to design combination regimens. These 6 classes include the nucleoside/nucleotide reverse transcriptase inhibitors (NRTIs), non-nucleoside reverse transcriptase inhibitors (NNRTIs), protease inhibitors (PIs), fusion inhibitors (FIs), CCR5 antagonists, and integrase strand transfer inhibitors (INSTIs).

The Panel provides recommendations for preferred, alternative, and acceptable regimens; regimens that may be acceptable but more definitive data are needed; and regimens that may be acceptable but should be used with caution (**Tables 5a and 5b**). Potential advantages and disadvantages of the components recommended as initial therapy for ARV-naïve patients are listed in **Table 6** to guide prescribers in choosing the regimen best suited for an individual patient. A list of agents or components not recommended for initial treatment can be found in **Table 7**.

CONSIDERATIONS WHEN SELECTING A FIRST ANTIRETROVIRAL REGIMEN FOR ANTIRETROVIRAL THERAPY-NAÏVE PATIENTS

Data Used for Making Recommendations

The Panel reviews clinical trial data published in peer-reviewed journals and data prepared by manufacturers for Food and Drug Administration (FDA) review. In selected cases, data presented in abstract format in major scientific meetings also are reviewed. The first criterion for selection is published information from a randomized, prospective clinical trial with an adequate sample size that demonstrates durable viral suppression and immunologic enhancement (as evidenced by increase in CD4 count). Few of these trials include clinical endpoints, such as development of AIDS-defining illness or death. Thus, assessment of regimen efficacy and potency is primarily based on surrogate marker endpoints (HIV RNA and CD4 responses). The Panel reviewed data from randomized clinical trials to arrive at preferred, alternative, or acceptable ratings in **Tables 5a and 5b**. "Preferred regimens" are those studied in randomized controlled trials and shown to have optimal and durable virologic efficacy, favorable tolerability and toxicity profiles, and ease of use. "Alternative regimens" are those regimens that are effective but have potential disadvantages when compared to preferred regimens. On the basis of individual patient characteristics and needs, a regimen listed as an alternative may actually be the preferred regimen in certain situations. Some regimens are classified as "Acceptable Regimens" because of reduced virologic activity, lack of efficacy data from large clinical trials, or other factors (such as greater toxicities, requiring additional testing, pill burden, or drug interaction potential) compared with preferred or alternative regimens.

Lastly, the Panel classified several regimens as "regimens that are acceptable but should be used with caution" because of some safety or efficacy concerns explained in **Table 5b.**

Factors to Consider When Selecting an Initial Regimen

Regimen selection should be individualized and should be based on a number of factors, including:

- comorbid conditions (e.g., cardiovascular disease, chemical dependency, liver disease, psychiatric disease, renal diseases, or tuberculosis);
- potential adverse drug effects;
- potential drug interactions with other medications;
- pregnancy or pregnancy potential;
- results of genotypic drug-resistance testing;
- gender and pretreatment CD4 count if considering nevirapine (NVP);
- HLA-B*5701 testing if considering abacavir (ABC);
- coreceptor tropism assay if considering maraviroc (MVC);
- patient adherence potential; and
- convenience (e.g., pill burden, dosing frequency, and food and fluid considerations).

Considerations for Therapies

A listing of characteristics (i.e., dosing, pharmacokinetics, and common adverse effects) of individual ARV agents can be found in **Appendix B, Tables 1–6**. Additionally, **Appendix B, Table 7** provides clinicians with ARV dosing recommendations for patients who have renal or hepatic insufficiency.

Possible regimens include combinations of two NRTIs with an NNRTI, a PI (preferably boosted with ritonavir [RTV]), an INSTI (namely raltegravir [RAL]) or a CCR5 antagonist (namely MVC). In clinical trials, NNRTI-, PI-, INSTI-, or CCR5 antagonist-based regimens have all resulted in suppression of HIV RNA levels and CD4 cell increases in a large majority of patients *[1-7]*. Some comparative data are available. (See below.)

Tables 5a and 5b include the Panel's recommendations for initial therapy.

Table 5a. Preferred and Alternative Antiretroviral Regimens for Antiretroviral Therapy-Naïve Patients (Updated January 10, 2011)

Selection of a regimen should be individualized based on virologic efficacy, toxicity, pill burden, dosing frequency, drug-drug interaction potential, resistance testing results, and comorbid conditions. Refer to **Table 6** for a list of advantages and disadvantages and **Appendix B, Tables 1–6** for dosing information for individual ARV agents listed below. The regimens in each category are listed in alphabetical order.

Preferred Regimens (Regimens with optimal and durable efficacy, favorable tolerability and toxicity profile, and ease of use) **The preferred regimens for nonpregnant patients are arranged by order of FDA approval of components other than nucleosides, thus, by duration of clinical experience.**	
NNRTI-Based Regimen • EFV/TDF/FTC[1] **(AI)** **PI-Based Regimens** *(in alphabetical order)* • ATV/r + TDF/FTC[1] **(AI)** • DRV/r (once daily) + TDF/FTC[1] **(AI)** **INSTI-Based Regimen** • RAL + TDF/FTC[1] **(AI)** **Preferred Regimen[2] for Pregnant Women** • LPV/r (twice daily) + ZDV/3TC[1] **(AI)**	**Comments** **EFV** should not be used during the first trimester of pregnancy or in women trying to conceive or not using effective and consistent contraception. **ATV/r** should not be used in patients who require >20 mg omeprazole equivalent per day. Refer to **Table 15a** for dosing recommendations regarding interactions between ATV/r and acid-lowering agents.
Alternative Regimens (Regimens that are effective and tolerable but have potential disadvantages compared with preferred regimens. An alternative regimen may be the preferred regimen for some patients.)	
NNRTI-Based Regimens *(in alphabetical order)* • EFV + (ABC or ZDV)/3TC[1] **(BI)** • NVP + ZDV/3TC[1] **(BI)** **PI-Based Regimens** *(in alphabetical order)* • ATV/r + (ABC or ZDV)/3TC[1] **(BI)** • FPV/r (once or twice daily) + either [(ABC or ZDV)/3TC[1]] or TDF/FTC[1] **(BI)** • LPV/r (once or twice daily) + either [(ABC or ZDV)/3TC[1]] or TDF/FTC[1] **(BI)**	**Comments** **NVP** • NVP should not be used in patients with moderate to severe hepatic impairment (Child-Pugh B or C)[3] • NVP should not be used in women with pre-ARV CD4 count >250 cells/mm^3 or men with pre-ARV CD4 count >400 cells/mm^3. **ABC** • ABC should not be used in patients who test positive for HLA-B*5701. • Use ABC with caution in patients with high risk of cardiovascular disease or with pretreatment HIV RNA >100,000 copies/mL. (See text.) **Once-daily LPV/r** is not recommended in pregnant women.

[1]3TC may substitute for FTC or vice versa.
[2]For more detailed recommendations on ARV use in an HIV-infected pregnant woman, refer to the ***Perinatal Guidelines*** available at **http://aidsinfo.nih.gov/guidelines**.
[3]Refer to **Appendix B, Table 7** for the criteria for Child-Pugh classification.

The following combinations in the recommended list above are available as fixed-dose combination formulations: ABC/3TC, EFV/TDF/FTC, LPV/r, TDF/FTC, and ZDV/3TC.

Acronyms: 3TC = lamivudine, ABC = abacavir, ATV = atazanavir, ATV/r = atazanavir/ritonavir, DRV = darunavir, DRV/r = darunavir/ritonavir, EFV = efavirenz, FPV = fosamprenavir, FPV/r = fosamprenavir/ritonavir, FTC = emtricitabine, INSTI = integrase strand transfer inhibitor, LPV = lopinavir, LPV/r = lopinavir/ritonavir, NNRTI = non-nucleoside reverse transcriptase inhibitor, NRTI = nucleos(t)ide reverse transcriptase inhibitor, NVP = nevirapine, PI = protease inhibitor, RAL = raltegravir, TDF = tenofovir, ZDV = zidovudine

Table 5b. Acceptable Antiretroviral Regimens for Treatment-Naïve Patients (Updated January 10, 2011)

Acceptable Regimens (CI) (Regimens that may be selected for some patients but are less satisfactory than preferred or alternative regimens) **and Regimens that may be Acceptable but more definitive data are needed (CIII)**	
NNRTI-Based Regimen • EFV + ddI + (3TC or FTC) **(CI)** **PI-Based Regimens** • ATV + (ABC or ZDV)/3TC[1] **(CI)** • DRV/r + (ABC or ZDV)/3TC[1] **(CIII)** **INSTI-Based Regimen** • RAL + (ABC or ZDV)/3TC[1] **(CIII)** **CCR5 Antagonist-Based Regimens** • MVC + ZDV/3TC[1] **(CI)** • MVC + TDF/FTC[1] or ABC/3TC[1] **(CIII)**	**Comments** **EFV + ddI + (FTC or 3TC)** has only been studied in small clinical trials. **ATV/r** is generally preferred over ATV. Unboosted ATV may be used when RTV boosting is not possible. **MVC** Tropism testing should be performed before initiation of therapy; only patients found to have only CCR5-tropic virus are candidates for MVC.
Regimens that may be acceptable but should be used with caution (Regimens that have demonstrated virologic efficacy in some studies but have safety, resistance, or efficacy concerns. See comments below.)	
NNRTI-Based Regimens • NVP + ABC/3TC[1] **(CIII)** • NVP + TDF/FTC[1] **(CIII)** **PI-Based Regimens** • FPV + [(ABC or ZDV)/3TC[1] or TDF/FTC[1]] **(CIII)** • SQV/r + TDF/FTC[1] **(CI)** • SQV/r + (ABC or ZDV)/3TC[1] **(CIII)**	**Comments** Use **NVP** and **ABC** together with caution because both can cause HSRs within first few weeks after initiation of therapy. Early virologic failure with high rates of resistance has been reported in some patients receiving **NVP + TDF + (3TC or FTC)**. Larger clinical trials are currently in progress. **FPV/r** is generally preferred over unboosted FPV. Virologic failure with unboosted FPV-based regimen may select mutations that confer cross resistance to DRV. **SQV/r** • SQV/r was associated with PR and QT prolongation in a healthy volunteer study. • Baseline ECG is recommended before initiation of SQV/r. • SQV/r is not recommended in patients with any of the following: 1. pretreatment QT interval >450 msec 2. refractory hypokalemia or hypomagnesemia 3. concomitant therapy with other drugs that prolong QT interval 4. complete AV block without implanted pacemaker 5. risk of complete AV block

[1]3TC maybe substituted with FTC or vice versa.

Acronyms: 3TC = lamivudine, ABC = abacavir, ATV = atazanavir, ATV/r = atazanavir/ritonavir, AV = atrioventricular, ddI = didanosine, DRV = darunavir, DRV/r = darunavir/ritonavir, ECG = electrocardiogram, EFV = efavirenz, FPV = fosamprenavir, FPV/r = fosamprenavir/ritonavir, FTC = emtricitabine, HSR = hypersensitivity reaction, INSTI = integrase strand transfer inhibitor, msec = millisecond, MVC = maraviroc, NNRTI = non-nucleoside reverse transcriptase inhibitor, NVP = nevirapine, PI = protease inhibitor, RAL = raltegravir, RTV = ritonavir, SQV = saquinavir, SQV/r = saquinavir/ritonavir, TDF = tenofovir, ZDV = zidovudine

NNRTI- versus PI- versus INSTI- versus CCR5 Antagonist-Based Regimens

EFV-based regimens have been compared with a variety of other regimens in clinical trials, including boosted or unboosted PI-based, RAL-based, and MVC-based regimens *[3-9]*. No regimen has proven superior to EFV-based regimens with respect to virologic responses.

NNRTI- versus PI-Based Regimens

RTV-boosted PI-based regimens have shown good virologic and immunologic responses but are often associated with more gastrointestinal symptoms, whereas EFV-based regimens are associated with more rash and central nervous system adverse effects. Both types of regimens may be associated with hepatic transaminase elevations *[10]*.

Drug resistance to most PIs requires multiple mutations in the HIV protease gene, and it seldom develops after early virologic failure *[11]*, especially when RTV boosting is used. Resistance to EFV or NVP, however, is conferred by a single mutation in the reverse transcriptase gene, and it develops rapidly after virologic failure *[11]*. An estimated 8% of newly infected patients in the United States carry NNRTI-resistant viruses *[12]*. Because of the concern for primary resistance in the ART-naïve population, genotypic testing results should be used to guide the selection of the initial ARV regimen. (See **Drug-Resistance Testing**.) In terms of convenience, the coformulated tablet of TDF, FTC, and EFV allows for once-daily dosing with a single tablet. Most PI-based regimens include RTV, may be dosed once or twice daily, and generally require more pills in the regimen, although the pill burden associated with PI-based regimens has decreased when compared with older PIs (for example, nelfinavir [NFV]or indinavir [IDV]). Drug-drug interactions are important with both kinds of regimens, but more clinically significant interactions are seen with RTV-boosted PI regimens.

Other Treatment Options

Another option for initial therapy is the combination of TDF, FTC, and RAL *[6]*. This combination has shown similar virologic efficacy as compared with a combination of TDF, FTC, and EFV up to 96 weeks *[13]* and is generally well tolerated. There are no clinical trial data comparing INSTI-based with PI-based regimens. RAL requires twice-daily dosing, has a low genetic barrier for selection of resistance mutations, and has had relatively limited use with other dual-NRTI combinations. MVC has been approved for use in ART-naïve patients, based on data from the MERIT study comparing MVC/zidovudine (ZDV)/lamivudine (3TC) with EFV/ZDV/3TC *[7]*.

The discussions below focus on the rationale for the Panel's recommendations, based on the efficacy, safety, and other characteristics of different agents within the individual drug classes.

NNRTI-BASED REGIMENS (1 NNRTI + 2 NRTIs)

Summary: NNRTI-Based Regimens

Four NNRTIs (delavirdine [DLV], EFV, etravirine [ETR], and NVP) are currently FDA approved.

NNRTI-based regimens have demonstrated virologic potency and durability. The major disadvantages of currently available NNRTIs involve prevalence of NNRTI-resistant viral strains in ART-naïve patients *[12, 14-16]* and the low genetic barrier of NNRTIs for development of resistance. Resistance testing should be performed for ART-naïve patients to guide therapy selection. (See **Drug-Resistance Testing**.) The first three approved NNRTIs (i.e., DLV, EFV, NVP) require only a single mutation to confer resistance, and cross resistance affecting these three NNRTIs is common. ETR, an NNRTI approved for ART-experienced patients, has *in vitro* activity against some viruses with mutations that confer resistance to DLV, EFV, and NVP *[17]*.

On the basis of clinical trial results and safety data, the Panel recommends either EFV or NVP as the NNRTI for initial ART. In most instances, EFV is preferred, based on its potency and tolerability (as discussed below). EFV should not be used in pregnant women (especially during the first trimester) or in women of childbearing potential who are planning to conceive or who are sexually active with men and not using effective and consistent contraception.

NVP may be used as an alternative to EFV for the initial NNRTI-based regimen in women with pretreatment CD4 counts ≤250 cells/mm^3 or in men with pretreatment CD4 counts ≤400 cells/mm^3 **(BI)**. (See discussion below.)

Among these four agents, DLV is dosed three times daily, has the least supportive clinical trial data, and appears to have the least antiviral activity. As such, DLV is **not recommended** as part of an initial regimen **(BIII)**. ETR has not been studied in large, randomized trials in ART-naïve participants. Thus, ETR **cannot be recommended** as part of initial therapy **(BIII)**.

Following is a more detailed discussion of preferred and alternative NNRTI-based regimens for initial therapy.

EFV as Preferred NNRTI

Large randomized, controlled trials and cohort studies of ART-naïve patients have demonstrated potent viral suppression in EFV-treated patients; a substantial proportion of these patients had HIV RNA <50 copies/mL during up to 7 years of follow-up *[1-2, 18]*. Studies that compared EFV-based regimens with other regimens demonstrated the combination of EFV with two NRTIs was superior virologically to some PI-based regimens, including indinavir (IDV) *[3]*, ritonavir-boosted lopinavir (LPV/r) *[4]*, and nelfinavir (NFV) *[8]* and to triple-NRTI–based regimens of ABC, ZDV, and 3TC or ABC, TDF, and 3TC *[19-20]*. EFV-based regimens also had comparable virologic activity when compared with NVP- *[21-22]*, atazanavir (ATV)- *[5]*, RAL- *[6]*, or MVC-based *[7]* regimens.

The ACTG 5142 study randomized patients to receive two NRTIs together with either EFV or LPV/r (or an NRTI-sparing regimen of EFV and LPV/r) *[4]*. The dual-NRTI and EFV regimen was associated with a better virologic response than the dual-NRTI and LPV/r regimen at 96 weeks, whereas the dual-NRTI with LPV/r regimen was associated with a better CD4 response and less drug resistance after virologic failure.

The 2NN trial compared EFV with NVP, both given with stavudine (d4T) and 3TC, in ART-naïve patients. Virologic responses were similar for both drugs, although NVP was associated with greater toxicity and did not meet criteria for noninferiority compared with EFV *[21]*.

Two major limitations of EFV are its central nervous system adverse effects, which usually resolve over a few weeks, and its potential teratogenic effects. In animal reproductive studies, EFV caused major congenital anomalies in the central nervous system in nonhuman primates at drug exposure levels similar to those achieved in humans *[23]*. Several cases of neural tube defects in human newborns of mothers exposed to EFV during the first trimester of pregnancy have been reported *[24-25]*. Therefore, EFV is not recommended in pregnant women during the first trimester of pregnancy or in women with high pregnancy potential (women of childbearing potential who are trying to conceive or who are sexually active with men and are not using effective and consistent contraception) **(AIII)**.

Studies that use EFV and dual-NRTI combinations (ABC, didanosine [ddI], d4T, TDF, or ZDV together with FTC or 3TC) show durable virologic activity, although there may be differences among the various combinations chosen. (See **Dual-NRTI Options**.) A single tablet coformulated with TDF, FTC, and EFV provides one-tablet, once-daily dosing and is currently the preferred NNRTI-based regimen **(AI)**.

NVP as Alternative NNRTI

In the 2NN trial, 70% of participants in the EFV arm and 65.4% in the twice-daily NVP arm had virologic suppression (defined as HIV RNA <50 copies/mL) at 48 weeks. This difference did not reach criteria necessary to demonstrate noninferiority of NVP *[21]*. Two deaths were attributed to NVP use. One resulted from fulminant hepatitis and one from staphylococcal sepsis as a complication of Stevens-Johnson syndrome.

In a randomized controlled trial, NVP was found to be noninferior to boosted ATV when combined with TDF/FTC *[26]*. This study enrolled only women and men with CD4 counts <250 cells/mm^3 and <400 cells/mm^3, respectively, the threshold recommended to reduce the incidence of hepatic toxicity (see below). Three smaller studies (n <100) have suggested more virologic failures than would be expected in ART-naïve participants who receive NVP plus TDF and either 3TC or FTC *[27-29]*. Pending published results from randomized trials, clinicians should closely monitor virologic responses if using this combination **(CIII)**.

Serious hepatic events have been observed when NVP was initiated in ART-naïve patients. These events generally occur within the first few weeks of treatment. In addition to experiencing elevated serum transaminases, approximately half of the patients also develop skin rash, with or without fever or flu-like symptoms. Retrospective analysis of reported events suggests that women with higher CD4 counts appear to be at highest risk *[30-31]*. A 12-fold higher incidence of symptomatic hepatic events was seen in women (including pregnant women) with CD4 counts >250 cells/mm^3 at the time of NVP initiation compared with women with CD4 counts ≤250 cells/mm^3 (11.0% vs. 0.9%). An increased risk was also seen in men with pretreatment CD4 counts >400 cells/mm^3 compared with men with pretreatment CD4 counts ≤400 cells/mm^3 (6.3% vs. 1.2%). Most of these patients had no identifiable underlying hepatic abnormalities. In some cases, hepatic injuries continued to progress despite discontinuation of NVP *[31-32]*. In contrast, other studies have not shown an association between baseline CD4 counts and severe NVP hepatotoxicity *[33-34]*. Symptomatic hepatic events have not been reported with single-dose NVP given to mothers or infants for prevention of perinatal HIV infection.

On the basis of the earlier safety data, the Panel recommends that NVP may be considered as an alternative to EFV as initial therapy for women with pretreatment CD4 counts ≤250 cells/mm^3 or in men with CD4 counts ≤400 cells/mm^3. Patients who experience CD4 count increases to levels above these thresholds as a result of NVP-containing therapy can safely continue therapy without an increased risk of adverse hepatic events *[35]*.

At the initiation of NVP, a 14-day lead-in period at a dosage of 200 mg once daily should be instituted before increasing to the maintenance dosage of 200 mg twice daily. Some experts recommend monitoring serum transaminases at baseline, prior to and 2 weeks after dose escalation, and then monthly for the first 18 weeks. Clinical and laboratory parameters should be assessed at each visit.

PI-BASED REGIMENS (RTV-BOOSTED OR UNBOOSTED PI + 2 NRTIs)

Summary: PI-Based Regimens

PI-based regimens have demonstrated more virologic potency and durability and higher barriers to resistance than NNRTI- and INSTI-based regimens. In patients who experience virologic failure while on their first PI-based regimen, few or no PI mutations are detected at failure. Each PI has its own virologic potency, adverse effect profile, and pharmacokinetic properties. The characteristics, advantages, and disadvantages of each PI can be found in **Table 6** and **Appendix B, Table 3**. In selecting a boosted PI-based regimen for an ART-naïve patient, clinicians should consider factors such as dosing frequency, food requirements, pill burden, daily RTV dose, drug interaction potential, baseline lipid profile, toxicity profile of the individual PI, and pregnancy status. (See the ***Perinatal Guidelines*** for specific recommendations in pregnancy *[36]*.)

A number of metabolic abnormalities, including dyslipidemia and insulin resistance, have been associated with PI use. The currently available PIs differ in their propensity to cause these metabolic complications, which are also dependent on the dose of RTV used as a pharmacokinetic boosting agent. Some studies have suggested that LPV/r, IDV, fosamprenavir (FPV), or FPV/r may be associated with increased rates of myocardial infarction (MI) or stroke *[37-38]*. It should be noted that in both studies, there were too few patients receiving ATV/r or DRV/r to be included in the analysis. Ritonavir-boosted saquinavir (SQV/r) can prolong the PR and QT intervals on electrocardiogram (ECG). The degree of QT prolongation is greater than that seen with some other boosted PIs. Therefore, SQV/r should be used with caution in patients at risk of or who use concomitant drugs that may potentiate these ECG abnormalities *[39]*.

The potent inhibitory effect of RTV on the cytochrome P (CYP) 450 3A4 isoenzyme has allowed the addition of low-dose RTV to other PIs as a pharmacokinetic booster to increase drug exposure and prolong plasma half-life of the active PI. This allows for reduced dosing frequency and/or pill burden, which may improve overall adherence to the regimen. The increased trough concentration (C_{min}) may improve the ARV activity of the primary PI, which can be beneficial when the patient harbors HIV strains with reduced susceptibility to the PI *[40-42]* and also may contribute to the lower risk of resistance upon virologic failure compared with unboosted PIs. The drawbacks associated with this strategy are the potential for increased risk of hyperlipidemia and a greater potential of drug-drug interactions from the addition of RTV. In patients without pre-existing PI resistance, there is growing support for the use of once-daily

boosted PI regimens that use only 100 mg per day of RTV because they tend to cause fewer gastrointestinal side effects and less metabolic toxicity than regimens that use RTV at a dose of 200 mg per day. In the case of RTV-boosted darunavir (DRV) (800/100 mg once daily) and ATV (300/100 mg once daily), there are large head-to-head trials demonstrating noninferiority or superiority compared with LPV/r, with less gastrointestinal and lipid toxicity.

The Panel uses the following criteria to distinguish between preferred versus alternative PIs in ART-naïve patients: (1) demonstrated superior or noninferior virologic efficacy when compared with at least one other PI-based regimen, with at least published 48-week data; (2) RTV-boosted PI with no more than 100 mg of RTV per day; (3) once-daily dosing; (4) low pill count; and (5) good tolerability. Using these criteria, the Panel recommends ATV + RTV (once daily) **(AI)** and DRV + RTV (once daily) **(AI)** as preferred PIs.

Preferred PI Components (in alphabetical order, by active PI component)

RTV-Boosted ATV (ATV/r). RTV boosting of ATV, given as two pills once daily, enhances the concentrations of ATV and improves virologic activity compared with unboosted ATV in a clinical trial *[43]*.

The CASTLE study compared once-daily ATV/r with twice-daily LPV/r, each in combination with TDF/FTC, in 883 ARV-naïve participants. In this open-label, noninferiority study, analysis at 48 weeks *[44]* and at 96 weeks *[45]* showed similar virologic and CD4 responses of the two regimens. More hyperbilirubinemia and less gastrointestinal toxicity were seen in the ATV/r arm. This study supports the designation of ATV/r + TDF/FTC as a preferred regimen.

The main adverse effect associated with ATV/RTV is indirect hyperbilirubinemia, with or without jaundice or scleral icterus, but without concomitant hepatic transaminase elevations. Several cases of nephrolithiasis have also been reported in patients who received RTV-boosted or unboosted ATV *[46]*. ATV/RTV requires acidic gastric pH for dissolution. Thus, concomitant use of drugs that raise gastric pH, such as antacids, H_2 antagonists, and particularly proton pump inhibitors, may impair absorption of ATV. **Table 15a** provides recommendations for how to use RTV-boosted ATV with these agents.

RTV-Boosted DRV (DRV/r). The ARTEMIS study compared DRV/r (800/100 mg once daily, three pills per day) with LPV/r (once or twice daily), both in combination with TDF/FTC, in a randomized, open-label, noninferiority trial. The study enrolled 689 ART-naïve participants. At 48 weeks, DRV/r was noninferior to LPV/r. The virologic response rates were lower in the LPV/r arm among those participants whose baseline HIV RNA levels were >100,000 copies/mL. Grades 2 to 4 adverse events, primarily diarrhea, were seen more frequently in LPV/r recipients *[47]*. At 96 weeks, virologic response to DRV/r was superior to response with LPV/r *[48]*.

Alternative PI Components (in alphabetical order, by active PI component)

RTV-Boosted FPV (FPV/r) (once or twice daily). FPV/r is recommended as an alternative PI. The KLEAN trial compared twice-daily FPV/r with LPV/r, each in combination with ABC and 3TC, in ART-naïve patients. At Weeks 48 and 144, similar percentages of subjects achieved viral loads of <400 copies/mL *[49-50]*. Clinical and laboratory adverse events did not differ between the regimens. In this study of ART-naïve participants, twice-daily FPV/r was noninferior to twice-daily LPV/r. In the KLEAN study, the occurrence of metabolic adverse effects was similar with boosted FPV and with LPV/r. Based on the above criteria for preferred PIs that favor once-daily regimens with no more than 100 mg/day of RTV, twice-daily FPV is now considered an alternative choice.

In a study comparing once-daily FPV/r (1,400 mg with RTV 200 mg once daily) with NFV *[51]*, similar virologic efficacy was reported in both arms. A comparative trial of once-daily FPV/r (1,400/100 mg) with once-daily ATV/r, both in combination with TDF/FTC, was conducted in 106 ARV-naïve participants *[52]*. Similar virologic and CD4 benefits were seen with both regimens. The small sample size of this study precludes the assessment of superior or noninferior virologic efficacy required for a preferred PI. Collectively, FPV/r regimens, with once- or twice-daily dosing, are recommended as alternatives.

RTV-Boosted LPV (LPV/r) (coformulated) (BI). LPV/r is the only available coformulated boosted PI. It can be given once or twice daily. However, the need for 200 mg/day of RTV, and the higher rate of gastrointestinal side

effects and hyperlipidemia when compared with boosted PIs using RTV 100 mg/day, make it an alternative rather than preferred PI for ART-naïve patients. Early studies showed that LPV/r was superior to NFV in maintaining suppressed viral loads *[53]*. A 7-year follow-up study of LPV/r and two NRTIs showed sustained virologic suppression in patients who were maintained on the originally assigned regimen *[54]*. Results of clinical trials that compared LPV/r with ATV/r, DRV/r, FPV/r, or SQV/r are discussed in the respective sections of this document. The ACTG 5142 study showed that the regimen of twice-daily LPV/r plus two NRTIs had decreased virologic efficacy when compared with EFV plus two NRTIs. However, the CD4 response was greater with LPV/r, and there was less drug resistance associated with virologic failure *[4]*.

Several trials have evaluated different formulations and dosages of LPV/r administered once or twice daily *[47, 55-56]*. In the largest trial that compared once-daily with twice-daily LPV/r, both in combination with TDF/FTC, 664 ART-naïve participants were randomized to receive once- or twice-daily soft-gel capsules or once- or twice-daily tablets for 8 weeks; at Week 8, all participants received the tablet formulation and maintained their same randomized dosing schedule *[57]*. At Week 48, 77% of once-daily and 76% of twice-daily LPV/r recipients achieved viral loads <50 copies/mL. Rates of moderate to severe drug-related diarrhea were similar between the two groups. In addition to diarrhea, major adverse effects of LPV/r include insulin resistance and hyperlipidemia, especially hypertriglyceridemia; these required pharmacologic management in some patients. In the D:A:D and French observational cohorts, cumulative use of LPV/r was associated with a slightly increased risk of MI *[37-38]*. Once-daily LPV/r should not be used in patients who have HIV mutations associated with PI resistance because higher LPV trough levels may be required to suppress resistant virus. LPV/r given twice daily is the preferred PI for use in pregnant women *[36]*. Once-daily dosing should not be used in this situation, especially during the third trimester, when LPV levels are expected to decline. For more detailed information regarding ART drug choices and related issues in pregnancy, see the ***Perinatal Guidelines*** *[36]*.

Acceptable PI-Based Component

ATV. Unboosted ATV is given once daily and has fewer adverse effects on lipid profiles than other available PIs. Three studies compared ATV-based combination regimens with either NFV- or EFV-based regimens. These studies established similar virologic efficacy among ATV 400 mg once daily and both comparator treatment groups in ARV-naïve patients after 48 weeks of therapy *[5, 43, 58-59]*. The ACTG 5175 trial compared three regimens in ART-naïve patients. The Data Safety Monitoring Board for this trial recommended that participants be unblinded and switched to alternative therapy if they were randomized to ATV + enteric-coated ddI + FTC because of an inferior virologic response when compared with the other two arms—once-daily EFV plus either ZDV/3TC (twice daily) or TDF/FTC (once daily) *[60]*. If unboosted ATV is prescribed for an ART-naïve patient, clinicians should consider using a dual-NRTI backbone other than ddI + FTC (or 3TC).

Unboosted ATV may be an initial therapy for patients when a once-daily regimen without RTV is desired and for patients with underlying risk factors indicating that hyperlipidemia may be particularly undesirable. ATV should be used with RTV-boosting if TDF or EFV are used concomitantly because these two agents can lower the concentrations of ATV. ATV requires acidic gastric pH for dissolution. Thus, concomitant use of drugs that raise gastric pH, such as antacids, H_2 antagonists, and proton pump inhibitors, may significantly impair ATV absorption. Proton pump inhibitors should not be used in patients who are taking unboosted ATV. H_2 antagonists and antacids should be used with caution and with careful dose separation. (See **Tables 14 and 15a**.)

PI Components that May be Acceptable but Should be Used with Caution (in alphabetical order, by active PI component)

FPV. In a study comparing unboosted FPV given twice daily with NFV, more participants randomized to FPV achieved viral suppression at 48 weeks than participants assigned to NFV, and greater differences were seen in those who had pretreatment viral loads >100,000 copies/mL *[61]*. However, virologic failure on unboosted FPV may select for resistance mutations that confer cross resistance to DRV *[62-63]*, a PI with an important role in management of ART-experienced patients. As such, FPV/r is preferred over unboosted FPV, and the unboosted strategy should be used with caution.

RTV-Boosted SQV (SQV/r). The GEMINI study compared SQV/r (1,000/100 mg twice daily) with LPV/r, both given twice daily, in combination with TDF/FTC given once daily, in 337 ART-naïve participants who were monitored over 48 weeks. Similar levels of viral suppression and increases in CD4 counts were seen in both arms *[64]*. Triglyceride levels were higher in the LPV/r arm. The SQV/r regimen has a higher pill burden and requires twice-daily dosing and 200 mg of RTV. In a healthy volunteer study, SQV/r use was associated with increases in both QT and PR intervals. The degree of QT prolongation was greater than that seen with some other boosted PIs. Rare cases of torsades de pointes and complete heart block have been reported in post-marketing surveillance. Based on these findings, an ECG is recommended prior to initiation of SQV/r. SQV/r is not recommended for patients with any of the following conditions: documented congenital or acquired QT prolongation, pretreatment QT interval of >450 milliseconds (msec), refractory hypokalemia or hypomagnesemia, complete atrioventricular (AV) block without implanted pacemakers, at risk of complete AV block, or receiving other drugs that prolong QT interval *[39]*. Based on these restrictions and because there are several other preferred or alternative PI options, the Panel recommends that SQV/r may be acceptable but should be used with caution in selected ARV-naïve patients. (See **Table 5b** for rating.)

INSTI-BASED REGIMENS (INSTI + 2 NRTIs)

RAL. RAL is an INSTI that is approved for use in ART-naïve patients, based on results of STARTMRK, a Phase III study that compared RAL (400 mg twice daily) with EFV (600 mg once daily), each in combination with TDF/FTC, in ART-naïve subjects. This multinational double-blind, placebo-controlled study enrolled 563 subjects with plasma HIV-1 RNA levels >5,000 copies/mL. At Week 48, similar numbers of subjects achieved HIV-1 RNA levels <50 copies/mL in both groups (86.1% and 81.9% for RAL and EFV, respectively, p <0.001 for noninferiority). CD4 counts rose by 189 cells/mm^3 in the RAL group versus 163 cells/mm^3 in the EFV group. Serious adverse events occurred at a similar frequency in both groups *[6]*. At 96 weeks, virologic and immunologic responses remained similar in both groups with no new safety concerns identified *[13]*. Based on these data, the Panel recommends RAL + TDF/FTC (or 3TC) as a preferred regimen for ART-naïve patients **(AI)**.

Comparisons of RAL-based regimen with other regimens in ART-naïve subjects have not yet been reported, and there is less experience with RAL than with EFV or boosted PIs for initial therapy. In addition, RAL must be administered twice daily, a potential disadvantage when compared with some other regimens. RAL, like EFV, has a lower genetic barrier to resistance than RTV-boosted PIs, and resistance mutations were observed at approximately the same frequency in the comparative trial. RAL use with other dual NRTIs (such as ABC/3TC or ZDV/3TC) may be acceptable, but more definitive data for these regimens are needed **(CIII)**.

CCR5 ANTAGONIST-BASED REGIMENS (CCR5-A + 2 NRTIs)

The MERIT study compared the CCR5 antagonist MVC with EFV, both in combination with ZDV/3TC, in a randomized, double-blinded trial in ART-naïve participants *[7]*. Only participants who had CCR5-tropic virus and had no evidence of resistance to any drugs used in the study were enrolled (n = 721). At 48 weeks, virologic suppression (defined as HIV RNA <400 copies/mL) was seen in 70.6% of MVC recipients and in 73.1% of EFV recipients, and HIV RNA <50 copies/mL was observed in 65.3% of MVC recipients and in 69.3% of EFV recipients. The HIV RNA <50 copies/mL results did not meet the criteria set by the investigators to demonstrate noninferiority for MVC in this study. CD4 count increased by an average of 170 cells/mm^3 in the MVC arm and by 144 cells/mm^3 in the EFV arm. Through 48 weeks, more participants discontinued MVC compared with EFV because of lack of efficacy (11.9% vs. 4.2%), whereas fewer participants discontinued MVC because of toxicity (4.2% vs. 13.6%). Follow-up results at 96 weeks demonstrated durable responses *[65]*. In a post-hoc reanalysis using a more sensitive viral tropism assay, 15% of patients with non-R5 screening virus were excluded from analysis, and their retrospective exclusion resulted in similar response rates in both arms, using either the HIV RNA criteria of <400 or <50 copies/mL. Based on the results, FDA approved MVC for use in regimens for ART-naïve patients. Because MVC requires twice-daily dosing, requires an expensive tropism assay prior to use, and there is little experience with regimens other than ZDV/3TC, the Panel recommends MVC + ZDV/3TC as an acceptable regimen for use in ART-naïve patients **(CI)**. Although the MERIT trial used ZDV/3TC as its NRTI backbone, many clinicians would favor the combination of MVC with TDF/FTC or ABC/3TC pending further data **(CIII)**.

DUAL-NRTI OPTIONS AS PART OF INITIAL COMBINATION THERAPY

Summary: Dual-NRTI Components

Dual NRTIs are commonly used in combination with an NNRTI, a PI (usually boosted with RTV), an INSTI, or a CCR5 antagonist. Most dual-NRTI combinations used in clinical practice consist of a primary NRTI plus 3TC or FTC. Both 3TC and FTC have few adverse effects but may select for the M184V resistance mutation, which confers high-level resistance to both drugs; a modest decrease in susceptibility to ddI and ABC; and improved susceptibility to ZDV, d4T, and TDF *[66]*.

All NRTIs except ddI can be taken without food restrictions. Adherence may be additionally improved with once-daily dosing (available for all NRTIs except d4T and ZDV) and with fixed-dosage combinations, such as ABC/3TC, TDF/FTC (with or without EFV), or ZDV/3TC.

The Panel's recommendations on specific dual-NRTI options are made on the basis of virologic potency and durability, short- and long-term toxicities, the propensity to select for resistance mutations, and dosing convenience.

Preferred Dual-NRTI

TDF/FTC (coformulated). TDF is a nucleotide analog with potent activity against both HIV and hepatitis B virus (HBV) and with a long intracellular half-life that allows for once-daily dosing. The fixed-dose combinations of TDF/FTC and TDF/FTC/EFV are both administered as one tablet once daily and are designed to improve adherence.

TDF, when used with either 3TC or FTC as part of an EFV-based regimen in ART-naïve patients, demonstrated potent virologic suppression *[18]* and was superior to ZDV/3TC in virologic efficacy up to 144 weeks *[67]*. In the 934 study, more participants in the ZDV/3TC arm developed loss of limb fat (as assessed by dual-energy x-ray absorptiometry [DXA]) and anemia at 96 and 144 weeks compared with the TDF/FTC arm *[67]*. Emergence of the M184V mutation was less frequent than with ZDV/3TC, and no participant had developed the K65R mutation after 144 weeks of therapy, in contrast to other studies in which TDF was combined with 3TC. TDF with FTC or 3TC has been studied in combination with several boosted PIs and RAL in randomized clinical trials; all such trials demonstrate good virologic benefit *[6, 44, 47, 52, 56]*.

TDF/FTC was compared with ABC/3TC in the ACTG 5202 study *[68]* and the HEAT trial *[69]*. Inferior virologic responses were observed in participants randomized to ABC/3TC who had a pretreatment HIV RNA >100,000 copies/mL. This was not confirmed by the results from the HEAT trial. (See the ABC/3TC section below for more detailed discussion.)

One randomized controlled trial found NVP to be noninferior to boosted ATV when combined with TDF/FTC *[26]*. Three small studies (n <100) have suggested more virologic failures than would be expected in ART-naïve participants who receive NVP plus TDF and either 3TC or FTC *[27-29]*. Pending published results from randomized trials, clinicians should closely monitor virologic responses if using this combination **(CIII)**.

Renal impairment, manifested by increases in serum creatinine, glycosuria, hypophosphatemia, and acute tubular necrosis, has been reported with TDF use *[70-71]*. Risk factors may include advanced HIV disease, greater treatment experience, and pre-existing renal impairment *[72]*. Renal function, urinalysis, and electrolytes should be monitored in patients who are on TDF. In patients who have some degree of pre-existing renal insufficiency (creatinine clearance [CrCl] <50 mL/min), TDF dosage adjustment is required. (See **Appendix B, Table 7** for dosage recommendations.) However, because no safety and efficacy data that use the dosage adjustment guidelines for renal dysfunction are available, the use of alternative NRTIs (especially ABC) may be preferred over dose-adjusted TDF in this setting.

TDF concentrations can be increased by some PIs, and studies have suggested a greater risk of renal dysfunction when TDF is used in PI-based regimens *[70, 73-76]*. TDF has been used in combination with PIs without renal toxicity in several clinical trials that involved patients who had CrCl >50–60 mL/min. Furthermore, in two randomized studies comparing TDF/FTC to ABC/3TC, participants receiving TDF/FTC experienced a significantly greater decline in bone mineral density *[77-78]*.

TDF plus either FTC or 3TC is the preferred NRTI combination, especially for patients coinfected with both HIV and HBV because these drugs have activity against both viruses. The use of a single HBV-active NRTI (e.g., 3TC or FTC) can lead to HBV resistance and is not recommended. (See **Hepatitis B (HBV)/HIV Coinfection**.)

Alternative Dual NRTIs (in alphabetical order)

ABC/3TC (coformulated) for Patients Who Test Negative for HLA-B*5701. ABC has the potential for serious hypersensitivity reactions (HSRs). Clinically suspected HSRs have been observed in 5%–8% of patients who start ABC. The risk of this reaction is highly associated with the presence of the HLA-B*5701 allele *[79-80]*. (See **HLA-B*5701 Screening**.) HLA-B*5701 testing should precede the use of ABC. ABC should not be given to patients who test positive for HLA-B*5701, and based on test results, ABC hypersensitivity should be noted on the patient's allergy list. Patients who test negative are less likely to experience HSR, but they should be counseled about the symptoms of the reaction.

In a comparative trial of ABC/3TC and ZDV/3TC (both given twice daily and combined with EFV), participants from both arms achieved similar virologic responses. The ABC-treated participants experienced a greater CD4 T-cell increase at 48 weeks *[81]*. The fixed-dose combination of ABC/3TC allows for one-pill, once-daily dosing.

The ACTG 5202 study, a randomized controlled trial in more than 1,800 participants, evaluated the efficacy and safety of ABC/3TC versus TDF/FTC when used in combination with either EFV or RTV-boosted ATV. Treatment randomization was stratified based on a screening HIV RNA of <100,000 copies/mL or ≥100,000 copies/mL. An independent Data Safety Monitoring Board recommended early termination of the ≥100,000 copies/mL stratification group because of a significantly shorter time to study-defined virologic failure in the ABC/3TC arm compared with the TDF/FTC arm *[68]*. Participants who had HIV RNA levels <100,000 copies/mL at study screening remained randomized and on study; a subsequent analysis of virological responses in this lower viral load stratum showed no significant differences between ABC/3TC and TDF/FTC *[82]*. In another study (HEAT), 688 participants received ABC/3TC or TDF/FTC in combination with once-daily LPV/r. A subgroup analysis according to baseline HIV RNA of <100,000 copies/mL or ≥100,000 copies/mL yielded similar percentages of participants with HIV RNA <50 copies/mL at 96 weeks for the two regimens (63% vs. 58% for those who had <100,000 copies/mL and 56% vs. 58% for those who had ≥100,000 copies/mL, respectively) *[69]*. The ASSERT study compared open label ABC/3TC with TDF/FTC in 385 HLA-B5701-negative, ART-naïve patients; all study subjects also received EFV. At 48 weeks, a lower proportion of the ABC/3TC-treated subjects had HIV RNA <50 copies/mL (59%) compared with those receiving TDF/FTC (71%, difference 11.6%, 95% confidence interval [CI] 2.2 to 21.1) *[83]*.

An association between ABC use and MI was first reported in the D:A:D cohort. This large, multinational observational study group found that recent (within 6 months) or current use of ABC, but not TDF, predicted an increased risk of MI, particularly in participants with pre-existing cardiac risk factors *[37, 84]*. In contrast, a pooled analysis of 52 clinical trials involving more than 9,500 participants who had received ABC showed no increase in MI risk *[85]*. Several additional retrospective studies have subsequently addressed this issue, but no consensus has been reached, either on the association or a possible mechanism *[86]*.

Pending additional data, ABC/3TC should be used with caution in individuals who have plasma HIV RNA levels ≥100,000 copies/mL as well as in persons at higher risk of cardiovascular disease. However, the combination of ABC/3TC remains a good alternative dual-NRTI option for some ART-naïve patients.

ZDV/3TC (coformulated). The dual-NRTI combination of ZDV/3TC has extensive durability, safety, and tolerability experience *[3, 5, 8, 19, 87-89]*. A fixed-dose combination of ZDV/3TC is available for one-tablet, twice-daily dosing. Selection of the 3TC-associated M184V mutation has been associated with increased susceptibility to ZDV. In a comparative trial of ABC/3TC versus ZDV/3TC (both given twice daily and combined with EFV), even though virologic responses were similar in both arms, the CD4 count increase was greater in the ABC/3TC-treated patients than in the ZDV/3TC-treated patients *[81]*.

Bone marrow suppression, manifested by macrocytic anemia and/or neutropenia, is seen in some patients. ZDV also is associated with gastrointestinal toxicity, fatigue, and possibly mitochondrial toxicity, including lactic acidosis/hepatic

steatosis and lipoatrophy. In the 934 study, participants who took ZDV had less limb fat at 96 and 144 weeks than those who took TDF, and there was a significant loss of fat among ZDV recipients between 48, 96, and 144 weeks *[67]*. In ACTG 5142, limb fat was lowest in patients treated with d4T, but those treated with ZDV had less limb fat than those treated with TDF *[10]*. Primarily because of its greater toxicity compared with TDF/FTC, ZDV/3TC is now considered an alternative rather than a preferred dual-NRTI option **(BI)**.

ZDV/3TC remains the preferred option in pregnant women. This dual NRTI has the most pharmacokinetic, safety, and efficacy data for both mother and newborn. For more detailed information regarding ARV drug choices and related issues in pregnancy, see the ***Perinatal Guidelines*** *[36]*.

Acceptable Dual NRTI

ddI + (FTC or 3TC). The FTC-301A trial tested ddI + FTC with EFV in ART-naïve patients and demonstrated potent virologic suppression *[90]*. The GESIDA 3903 study compared ddI/3TC with ZDV/3TC, combined with EFV *[91]*. At 48 weeks, virologic response for ddI/3TC was noninferior to ZDV/3TC.

The ACTG 5175 trial compared three regimens in ART-naïve patients. The Data Safety Monitoring Board for this trial recommended that participants be unblinded and switched to alternative therapy if they were randomized to a regimen of ATV + enteric-coated ddI + FTC because of an inferior virologic response compared with the other two arms (once-daily EFV plus either ZDV/3TC twice daily or TDF/FTC once daily) *[60]*. Alternative PIs should be considered if ddI + (FTC or 3TC) are used. ddI use also is associated with an increased risk of pancreatitis, peripheral neuropathy, other mitochondria-associated toxicities, and possibly noncirrhotic portal hypertension *[92]*. In the D:A:D study of MI risk, the use of ddI within the previous 6 months was associated with an increased risk of MI, compared with the use of other NRTIs *[84]*. This increase in cardiovascular risk was not seen in other cohort studies *[93]*.

Based on the limited clinical trial experience with the use of ddI + 3TC (or FTC) with another ARV drug other than EFV, the unfavorable results from ACTG 5175, and the many side effects associated with ddI, the Panel considers it an acceptable but inferior option and only to be used with EFV **(CI)**.

NRTIs and Hepatitis B Virus (HBV). Three of the current NRTIs—FTC, 3TC, and TDF—have activity against HBV. Most HBV/HIV coinfected patients should use coformulated TDF/FTC (or TDF + 3TC) as their NRTI backbone to provide additional activity against HBV and to avoid selection of HBV mutation that confers resistance to 3TC/FTC. It is important to note that patients who have HBV/HIV coinfection may be at risk of acute exacerbation of hepatitis after initiation or upon discontinuation of TDF, 3TC, or FTC *[94-96]*. Thus, these patients should be monitored closely for clinical or chemical hepatitis if these drugs are initiated or discontinued. (See **Hepatitis B (HBV)/HIV Coinfection** and **Initiating Antiretroviral Therapy**.)

ALL-NRTI REGIMENS

Several clinical trials that studied triple-NRTI regimens have shown suboptimal virologic activity *[19-20, 97-100]*.

ABC/3TC/ZDV (coformulated). ABC/3TC/ZDV is the only triple-NRTI combination for which randomized, controlled trials are available. ABC/3TC/ZDV demonstrated comparable ARV activity to IDV-based *[88-89]* and NFV-based regimens *[100]* but was inferior virologically to an EFV-based regimen *[19]*. This combination is **generally not recommended (BI)** and should be used only when a preferred, an alternative, or an acceptable NNRTI-, PI-, or INSTI-based regimen is less desirable because of concerns about toxicities, drug interactions, or regimen complexity.

ZDV/3TC + TDF. The DART study demonstrated that the combination of ZDV/3TC + TDF has antiviral activity *[101]*; however, comparative data with standard regimens are not available and therefore this combination **cannot be recommended** in routine clinical practice **(BIII)**.

ZDV/3TC + ABC + TDF. A quadruple-NRTI regimen of ZDV/3TC + ABC + TDF first showed comparable virologic responses to an EFV-based regimen in a small pilot study *[102]*. A larger study randomized 322 subjects to receive TDF/FTC combined with EFV, ATV/RTV, or a quadruple-NRTI regimen with ZDV and ABC. Although the

threshold of noninferiority for the protocol-defined virologic response was satisfied by the quadruple-NRTI regimen, the proportion of patients reaching HIV RNA ≤50 copies/mL was lower with the quadruple-NRTI regimen and the rate of serious toxicity was twice as high as that observed with the EFV-based regimen *[103]*. Thus, this regimen **cannot be recommended (BI)**.

Table 6. Advantages and Disadvantages of Antiretroviral Components Recommended as Initial Antiretroviral Therapy (Updated January 10, 2011)

ARV Class	ARV Agent(s)	Advantages	Disadvantages
NNRTI (in alphabetical order)		**NNRTI Class Advantages:** • Long half-lives	**NNRTI Class Disadvantages:** • Low genetic barrier to resistance (single mutation confers resistance for EFV, NVP, and DLV); greater risk of resistance at the time of failure or treatment interruption • Potential for cross resistance • Skin rash • Potential for CYP450 drug interactions (See Tables 14, 15b, and 16b.) • Transmitted resistance to NNRTIs more common than resistance to PIs
	EFV	• Virologic responses equivalent or superior to all comparators to date • Lowest pill burden; once-daily dosing • Fixed-dose combination with TDF/FTC	• Neuropsychiatric side effects • Teratogenic in nonhuman primates, and several cases of neural tube defect reported in infants of women with first-trimester exposure. EFV is contraindicated in first trimester of pregnancy; avoid use in women with pregnancy potential. • Dyslipidemia
	NVP	• No food effect • Fewer lipid effects than EFV	• Higher incidence of rash than with other NNRTIs, including rare but serious hypersensitivity reactions (Stevens-Johnson syndrome or toxic epidermal necrolysis) • Higher incidence of hepatotoxicity than with other NNRTIs, including serious and even fatal cases of hepatic necrosis • Contraindicated in patients with moderate or severe (Child-Pugh B or C) hepatic impairment • Some data suggest that ART-naïve patients with high pre-NVP CD4 counts (>250 cells/mm^3 for females, >400 cells/mm^3 for males) are at higher risk of symptomatic hepatic events. NVP is not recommended in these patients unless benefit clearly outweighs risk. • Early virologic failure of NVP + TDF + (FTC or 3TC) in small clinical trials • Fewer clinical trial data than for EFV
PI (in alphabetical order)		**PI Class Advantages:** • Higher genetic barrier to resistance • PI resistance uncommon with failure (boosted PIs)	**PI Class Disadvantages:** • Metabolic complications (e.g., dyslipidemia, insulin resistance, hepatotoxicity) • Gastrointestinal adverse effects • CYP3A4 inhibitors and substrates: potential for drug interactions (more pronounced with RTV-based regimens) (See Tables 14 and 15a.)
	ATV	• Fewer adverse effects on lipids than other PI • Once-daily dosing • Low pill burden (two pills per day) • Good GI tolerability • Signature mutation (I50L) not associated with broad PI cross resistance	• Indirect hyperbilirubinemia sometimes leading to jaundice or scleral icterus • PR interval prolongation: generally inconsequential unless combined with another drug with similar effect • Cannot be coadministered with TDF, EFV, or NVP (See ATV/r.) • Nephrolithiasis • Skin rash • Food requirement • Absorption depends on food and low gastric pH (See Table 15a for detailed information regarding interactions with H2 antagonists, antacids, and PPIs.)
	ATV/r	• RTV boosting: higher trough ATV concentration and greater antiviral effect • Once-daily dosing • Low pill burden (two pills per day)	• More adverse effects on lipids than unboosted ATV • More hyperbilirubinemia and jaundice than unboosted ATV • Food requirement • Absorption depends on food and low gastric pH (See Table 15a for interactions with H_2 antagonists, antacids, and PPIs.) • RTV boosting required with TDF and EFV. With EFV, use ATV 400 mg and RTV 100 mg once daily (PI-naïve patients only). • Should not be coadministered with NVP

Table 6. Advantages and Disadvantages of Antiretroviral Components Recommended as Initial Antiretroviral Therapy
Page 2 of 3

ARV Class	ARV Agent(s)	Advantages	Disadvantages
	DRV/r	• Once-daily dosing	• Skin rash • Food requirement
	FPV	• No food effect	• Skin rash • Potential for PI resistance with failure, including emergence of mutations that can cause DRV cross resistance
	FPV/r	• Twice-daily dosing resulted in efficacy comparable to LPV/r • RTV boosting: higher trough APV concentration and greater antiviral effect • Once-daily dosing possible with RTV 100 mg or 200 mg daily • No food effect	• Skin rash • Hyperlipidemia • Once-daily dosing results in lower APV concentrations than twice-daily dosing • For FPV 1,400 mg + RTV 200 mg: requires 200 mg of RTV and no coformulation • Fewer data on FPV 1,400 mg + RTV 100 mg dose than on DRV/r and ATV/r
	LPV/r	• Coformulated • No food requirement • Recommended PI in pregnant women (twice daily only) • Greater CD4 count increase than with EFV-based regimens	• Requires 200 mg per day of RTV • Lower drug exposure in pregnant women—may need dose increase in third trimester • Once-daily dosing not recommended in pregnant women • Once-daily dosing: lower trough concentration than twice-daily dosing • Possible higher risk of MI associated with cumulative use of LPV/r • PR and QT interval prolongation have been reported. Use with caution in patients at risk of cardiac conduction abnormalities or receiving other drugs with similar effect.
	SQV/r	• Efficacy similar to LPV/r with less hyperlipidemia	• Highest pill burden among available PI regimens (6 pills per day) • Requires 200 mg of RTV • Food requirement • PR and/or QT interval prolongations in a healthy volunteer study • Pretreatment ECG recommended • SQV/r is not recommended for patients with any of the following conditions: (1) congenital or acquired QT prolongation; (2) pretreatment ECG >450 msec; (3) on concomitant therapy with other drugs that prolong QT interval; (4) complete AV block without implanted pacemakers; (5) risk of complete AV block.
INSTI	**RAL**	• Virologic response noninferior to EFV • Fewer drug-related adverse events and lipid changes than EFV • No food effect • Fewer drug-drug interactions than PI- or NNRTI-based regimens	• Less long-term experience in ART-naïve patients than with boosted PI- or NNRTI-based regimens • Twice-daily dosing • Lower genetic barrier to resistance than with boosted PI-based regimens • No data with NRTIs other than TDF/FTC in ART-naïve patients
CCR5 Antagonist	**MVC**	• Virologic response noninferior to EFV in post-hoc analysis of MERIT study (See text.) • Fewer adverse effects than EFV	• Requires viral tropism testing prior to initiation of therapy with additional cost and possible delay in initiation of therapy • More MVC-treated than EFV-treated patients discontinued therapy due to lack of efficacy in MERIT study • Less long-term experience in ART-naïve patients than with boosted PI- or NNRTI-based regimens • Limited experience with 2-NRTI other than ZDV/3TC • Twice-daily dosing • CYP 3A4 substrate, dosing depends on presence or absence of concomitant CYP3A4 inducer(s) or inhibitor(s)
Dual NRTIs		**Dual-NRTI Class Advantage:** Established backbone of combination ART	**Dual-NRTI Class Disadvantage:** Rare but serious cases of lactic acidosis with hepatic steatosis reported with d4T, ddI, and ZDV

Table 6. Advantages and Disadvantages of Antiretroviral Components Recommended as Initial Antiretroviral Therapy

Dual-NRTI pairs (in alphabetical order)	**ABC/3TC**	• Virologic response noninferior to ZDV/3TC • Better CD4 count response than with ZDV/3TC • Once-daily dosing • Coformulation • No food effect • No cumulative TAM-mediated resistance	• Potential for ABC HSR in patients with HLA-B*5701 • Potential for increased cardiovascular events, especially in patients with cardiovascular risk factors • Inferior virologic responses when compared with TDF/FTC in patients with baseline HIV RNA >100,000 copies/mL in ACTG 5202 study; however, this was not seen in the HEAT study.
	ddI + (3TC or FTC)	• Once-daily dosing • No cumulative TAM-mediated resistance	• Peripheral neuropathy, pancreatitis • Reports of noncirrhotic portal hypertension • Food effect; must be taken on an empty stomach • Requires dosing separation from some PIs • Increase in toxicities when used with ribavirin, TDF, d4T, or hydroxyurea • Preliminary data showed inferior virologic responses of ATV/ddI/FTC when compared with EFV/ZDV/3TC or EFV/TDF/FTC. Combination of ATV/ddI/FTC should be avoided.
	TDF/FTC or TDF + 3TC	• Better virologic responses than with ZDV/3TC • Better virologic responses than with ABC/3TC in patients with baseline HIV RNA >100,000 copies/mL in ACTG 5202 study; however, this was not seen in the HEAT study. • Active against HBV; recommended dual-NRTI for HBV/HIV coinfection • Once-daily dosing • No food effect • Coformulated (TDF/FTC) and (EFV/TDF/FTC) • No cumulative TAM-mediated resistance	• Potential for renal impairment, including rare reports of Fanconi syndrome and acute renal insufficiency • Early virologic failure of NVP + TDF + (FTC or 3TC) in small clinical trials • Potential for decrease in bone mineral density
	ZDV/3TC	• Coformulated (ZDV/3TC and ZDV/3TC/ABC) • No food effect (although better tolerated with food) • Preferred 2 NRTI in pregnant women	• Bone marrow suppression, especially anemia and neutropenia • GI intolerance, headache • Mitochondrial toxicity, including lipoatrophy, lactic acidosis, hepatic steatosis • Inferior to TDF/FTC in combination with EFV • Diminished CD4 T-cell responses compared with ABC/3TC

Acronyms: 3TC = lamivudine, ABC = abacavir, ART = antiretroviral therapy, ARV = antiretroviral, ATV = atazanavir, ATV/r = atazanavir/ritonavir, AV = atrioventricular, CYP = cytochrome P, ddI = didanosine, DLV = delavirdine, DRV/r = darunavir/ritonavir, ECG = electrocardiogram, EFV = efavirenz, FPV = fosamprenavir, FPV/r = fosamprenavir/ ritonavir, FTC = emtricitabine, GI = gastrointestinal, HBV = hepatitis B virus, HSR = hypersensitivity reaction, INSTI = integrase strand transfer inhibitor, LPV/r = lopinavir/ritonavir, MI = myocardial infarction, msec = milliseconds, MVC = maraviroc, NNRTI = non-nucleoside reverse transcriptase inhibitor, NRTI = nucleoside reverse transcriptase inhibitor, NVP = nevirapine, PI = protease inhibitor, PPI = proton pump inhibitor, SQV/r = saquinavir/ritonavir, TAM = thymidine analogue mutation, TDF = tenofovir, ZDV = zidovudine

Table 7. Antiretroviral Components Not Recommended as Initial Therapy
(Updated December 1, 2009)

ARV Drugs or Components (in alphabetical order)	**Reasons for NOT recommending as initial therapy**
ABC/3TC/ZDV (coformulated) as triple-NRTI combination regimen **(BI)**	• Inferior virologic efficacy
ABC + 3TC + ZDV + TDF as quadruple-NRTI combination **(BI)**	• Inferior virologic efficacy
ABC + ddI **(BIII)**	• Insufficient data in ART-naïve patients
ABC + TDF **(BIII)**	• Insufficient data in ART-naïve patients
DRV (unboosted)	• Use without RTV has not been studied
DLV **(BII)**	• Inferior virologic efficacy • Inconvenient (three times daily) dosing
ddI + TDF **(BII)**	• High rate of early virologic failure • Rapid selection of resistance mutations • Potential for immunologic nonresponse/CD4 T-cell decline • Increased ddI drug exposure and toxicities
T-20 **(BIII)**	• No clinical trial experience in ART-naïve patients • Requires twice-daily subcutaneous injections
ETR **(BIII)**	• Insufficient data in ART-naïve patients
IDV (unboosted) **(BIII)**	• Inconvenient dosing (three times daily with meal restrictions) • Fluid requirement
IDV (RTV-boosted) **(BIII)**	• High incidence of nephrolithiasis
NFV **(BI)**	• Inferior virologic efficacy • High incidence of diarrhea
RTV as sole PI **(BIII)**	• High pill burden • Gastrointestinal intolerance
SQV (unboosted) **(BI)**	• Inferior virologic efficacy
d4T + 3TC **(BI)**	• Significant toxicities including lipoatrophy; peripheral neuropathy; and hyperlactatemia, including symptomatic and life-threatening lactic acidosis, hepatic steatosis, and pancreatitis
TPV (ritonavir-boosted) **(BI)**	• Inferior virologic efficacy

Acronyms: 3TC = lamivudine, ABC = abacavir, ARV = antiretroviral, d4T = stavudine, ddI = didanosine, DLV = delavirdine, DRV = darunavir, ETR = etravirine; IDV = indinavir, IDV/r = ritonavir-boosted indinavir, NFV = nelfinavir, NRTI = nucleoside reverse transcriptase inhibitor, RTV = ritonavir, SQV = sacquinavir, T-20 = enfuvirtide, TDF = tenofovir, TPV = tipranavir, ZDV = zidovudine

What Not to Use (January 10, 2011)

Some antiretroviral (ARV) regimens or components are not generally recommended because of suboptimal antiviral potency, unacceptable toxicities, or pharmacologic concerns. These are summarized below.

ANTIRETROVIRAL REGIMENS NOT RECOMMENDED

Monotherapy with nucleoside reverse transcriptase inhibitor (NRTI). Single-NRTI therapy does not demonstrate potent and sustained antiviral activity and **should not be used (AII)**. For prevention of mother-to-child transmission (PMTCT), zidovudine (ZDV) monotherapy is not recommended but might be considered in certain unusual circumstances in women with HIV RNA <1,000 copies/mL, although the use of a potent combination regimen is preferred. (See ***Perinatal Guidelines*** *[1]*, available at **http://aidsinfo.nih.gov**.)

Single-drug treatment regimens with a ritonavir (RTV)-boosted protease inhibitor (PI), either lopinavir (LPV) *[2]*, atazanavir (ATV) *[3]*, or darunavir (DRV) *[4-5]* are under investigation with mixed results, and **cannot be recommended** outside of a clinical trial at this time.

Dual-NRTI regimens. These regimens **are not recommended** because they have not demonstrated potent and sustained antiviral activity compared with triple-drug combination regimens **(AI)** *[6]*.

Triple-NRTI regimens. In general, triple-NRTI regimens other than abacavir/lamivudine/zidovudine (ABC/3TC/ZDV) **(BI)** and possibly lamivudine/zidovudine + tenofovir (3TC/ZDV + TDF) **(BII) should not be used** because of suboptimal virologic activity *[7-9]* or lack of data **(AI)**.

ANTIRETROVIRAL COMPONENTS NOT RECOMMENDED

Atazanavir (ATV) + indinavir (IDV). Both of these PIs can cause Grade 3 to 4 hyperbilirubinemia and jaundice. Additive adverse effects may be possible when these agents are used concomitantly. Therefore, these two PIs **are not recommended** for combined use **(AIII)**.

Didanosine (ddI) + stavudine (d4T). The combined use of ddI and d4T as a dual-NRTI backbone can result in a high incidence of toxicities, particularly peripheral neuropathy, pancreatitis, and lactic acidosis *[10-13]*. This combination has been implicated in the deaths of several HIV-infected pregnant women secondary to severe lactic acidosis with or without hepatic steatosis and pancreatitis *[14]*. Therefore, the combined use of ddI and d4T **is not recommended (AII)**.

Didanosine (ddI) + tenofovir (TDF). Use of ddI + TDF may increase ddI concentrations *[15]* and serious ddI-associated toxicities including pancreatitis and lactic acidosis *[16-17]*. These toxicities may be lessened by ddI dose reduction. The use of this combination has also been associated with immunologic nonresponse or CD4 cell decline despite viral suppression *[18-19]*, high rates of early virologic failure *[20-21]*, and rapid selection of resistance mutations *[20, 22]*. Because of these adverse outcomes, this dual-NRTI combination **is not generally recommended (AII)**. Clinicians caring for patients who are clinically stable on regimens containing ddI + TDF should consider altering the NRTIs to avoid this combination.

Two-non-nucleoside reverse transcriptase inhibitor (2-NNRTI) combinations. In the 2NN trial, ARV-naïve participants were randomized to receive once- or twice-daily nevirapine (NVP) versus efavirenz (EFV) versus EFV plus NVP, all combined with d4T and 3TC *[23]*. A higher frequency of clinical adverse events that led to treatment discontinuation was reported in participants randomized to the two-NNRTI arm. Both EFV and NVP may induce metabolism of etravirine (ETR), which leads to reduction in ETR drug exposure *[24]*. Based on these findings, the Panel **does not recommend using two NNRTIs in combination in any regimen (AI)**.

Efavirenz (EFV) in first trimester of pregnancy and in women with significant childbearing potential. EFV use was associated with significant teratogenic effects in nonhuman primates at drug exposures similar to those representing human exposure. Several cases of congenital anomalies have been reported after early human gestational exposure to EFV *[25-26]*. EFV **should be avoided** in pregnancy, particularly during the first trimester, and in women of childbearing potential who are trying to conceive or who are not using effective and consistent contraception **(AIII)**. If no other ARV options are available for the woman who is pregnant or at risk of becoming pregnant, the provider should consult with a clinician who has expertise in both HIV infection and pregnancy. (See ***Perinatal Guidelines*** *[1]*, available at **http://aidsinfo.nih.gov**.)

Emtricitabine (FTC) + lamivudine (3TC). Both of these drugs have similar resistance profiles and have minimal additive antiviral activity. Inhibition of intracellular phosphorylation may occur *in vivo*, as seen with other dual-cytidine analog combinations *[27]*. These two agents **should not be used** as a dual-NRTI combination **(AIII)**.

Etravirine (ETR) + unboosted PI. ETR may induce the metabolism and significantly reduce the drug exposure of unboosted PIs. Appropriate doses of the PIs have not been established *[24]* **(AII)**.

Etravirine (ETR) + ritonavir (RTV)-boosted atazanavir (ATV) or fosamprenavir (FPV). ETR may alter the concentrations of these PIs. Appropriate doses of the PIs have not been established *[24]* **(AII)**.

Etravirine (ETR) + ritonavir (RTV)-boosted tipranavir (TPV). RTV-boosted TPV significantly reduces ETR concentrations. These drugs **should not be coadministered** *[24]* **(AII)**.

Nevirapine (NVP) initiated in ARV-naïve women with CD4 counts >250 cells/mm^3 or in ARV-naïve men with CD4 counts >400 cells/mm^3. Greater risk of symptomatic hepatic events, including serious and life-threatening events, has been observed in these patient groups. NVP **should not be initiated** in these patients **(BI)** unless the benefit clearly outweighs the risk *[28-30]*. Patients who experience CD4 count increases to levels above these thresholds as a result of antiretroviral therapy (ART) can be safely switched to NVP *[31]*.

Unboosted darunavir (DRV), saquinavir (SQV), or tipranavir (TPV). The virologic benefit of these PIs has been demonstrated only when they were used with concomitant RTV. Therefore, use of these agents as part of a combination regimen **without RTV is not recommended (AII)**.

Stavudine (d4T) + zidovudine (ZDV). These two NRTIs **should not be used** in combination because of antagonism demonstrated *in vitro [32]* and *in vivo [33]* **(AII)**.

Table 8. Antiretroviral Regimens or Components That Should Not Be Offered At Any Time
(Updated January 10, 2011)

	Rationale	Exception
Antiretroviral Regimens Not Recommended		
Monotherapy with NRTI (AII)	• Rapid development of resistance • Inferior ARV activity when compared with combination of three or more ARV agents	• No exception
Dual-NRTI regimens (AI)	• Rapid development of resistance • Inferior ARV activity when compared with combination of three or more ARV agents	• No exception
Triple-NRTI regimens (AI) except for ABC/ZDV/3TC (BI) or possibly TDF + ZDV/3TC (BII)	• High rate of early virologic nonresponse seen when triple-NRTI combinations, including ABC/TDF/3TC and TDF/ddI/3TC, were used as initial regimen in ART-naïve patients. • Other triple-NRTI regimens have not been evaluated.	• ABC/ZDV/3TC (BI) and possibly TDF + ZDV/3TC (BII) in patients in whom other combinations are not desirable
Antiretroviral Components Not Recommended as Part of an Antiretroviral Regimen		
ATV + IDV (AIII)	• Potential additive hyperbilirubinemia	• No exception
ddI + d4T (AII)	• High incidence of toxicities: peripheral neuropathy, pancreatitis, and hyperlactatemia • Reports of serious, even fatal, cases of lactic acidosis with hepatic steatosis with or without pancreatitis in pregnant women	• When no other ARV options are available and potential benefits outweigh the risks **(BIII)**
ddI + TDF (AII)	• Increased ddI concentrations and serious ddI-associated toxicities • Potential for immunologic nonresponse and/or CD4 cell count decline • High rate of early virologic failure • Rapid selection of resistance mutations at failure	• Clinicians caring for patients who are clinically stable on regimens containing TDF + ddI should consider altering the NRTIs to avoid this combination.
2-NNRTI combination (AI)	• When EFV combined with NVP, higher incidence of clinical adverse events seen when compared with either EFV- or NVP-based regimen. • Both EFV and NVP may induce metabolism and may lead to reductions in ETR exposure; thus, they should not be used in combination with ETR.	• No exception
EFV in first trimester of pregnancy or in women with significant childbearing potential (AIII)	• Teratogenic in nonhuman primates	• When no other ARV options are available and potential benefits outweigh the risks **(BIII)**
FTC + 3TC (AIII)	• Similar resistance profiles • No potential benefit	• No exception
ETR + unboosted PI (AII)	• ETR may induce metabolism of these PIs; appropriate doses not yet established	• No exception
ETR + RTV-boosted ATV or FPV (AII)	• ETR may alter the concentrations of these PIs; appropriate doses not yet established	• No exception
ETR + RTV-boosted TPV (AII)	• ETR concentration may be significantly reduced by RTV-boosted TPV	• No exception
NVP in ARV-naïve women with CD4 count >250 cells/mm^3 or men with CD4 count >400 cells/mm^3 (BI)	• High incidence of symptomatic hepatotoxicity	• If no other ARV option available; if used, patient should be closely monitored
d4T + ZDV (AII)	• Antagonistic effect on HIV-1	• No exception
Unboosted DRV, SQV, or TPV (AII)	• Inadequate bioavailability	• No exception

Acronyms:
3TC = lamivudine, ABC = abacavir, ATV = atazanavir, d4T = stavudine, ddI = didanosine, DRV = darunavir, EFV = efavirenz, ETR = etravirine, FPV = fosamprenavir, FTC = emitricitabine, IDV = indinavir, NVP = nevirapine, RTV = ritonavir, SQV = saquinavir, TDF = tenofovir, TPV = tipranavir, ZDV = zidovudine

Management of the Treatment-Experienced Patient

VIROLOGIC AND IMMUNOLOGIC FAILURE (Updated January 10, 2011)

Panel's Recommendations:

- ***Assessing and managing an antiretroviral (ARV)-experienced patient experiencing failure of antiretroviral therapy (ART) is complex. Expert advice is critical and should be sought.***
- ***Evaluation of virologic failure should include an assessment of the severity of the patient's HIV disease, ART history, use of concomitant medications with consideration of adverse drug interactions with ARV agents, HIV RNA and CD4 T-cell count trends over time, and prior drug-resistance testing results.***
- ***Drug-resistance testing should be obtained while the patient is taking the failing ARV regimen or within 4 weeks of treatment discontinuation (AII).***
- ***The goal of treatment for ARV-experienced patients with drug resistance who are experiencing virologic failure is to re-establish virologic suppression (e.g., HIV RNA <48 copies/mL) (AI).***
- ***To design a new regimen, the patient's treatment history and past and current resistance test results should be used to identify at least two (preferably three) fully active agents to combine with an optimized background ARV regimen (AI). A fully active agent is one that is likely to have ARV activity on the basis of the patient's treatment history, drug-resistance testing, and/or a novel mechanism of action.***
- ***In general, adding a single, fully active ARV in a new regimen is not recommended because of the risk of rapid development of resistance (BII).***
- ***In patients with a high likelihood of clinical progression (e.g., CD4 count <100 cells/mm^3) and limited drug options, adding a single drug may reduce the risk of immediate clinical progression, because even transient decreases in HIV RNA and/or transient increases in CD4 cell counts have been associated with clinical benefits (CI).***
- ***For some highly ART-experienced patients, maximal virologic suppression is not possible. In this case, ART should be continued (AI) with regimens designed to minimize toxicity, preserve CD4 cell counts, and avoid clinical progression.***
- ***Discontinuing or briefly interrupting therapy in a patient with viremia may lead to a rapid increase in HIV RNA and a decrease in CD4 cell count and increases the risk of clinical progression. Therefore, this strategy is not recommended (AI).***
- ***In the setting of virologic suppression, there is no consensus on how to define or treat immunologic failure.***

Rating of Recommendations: A = Strong; B = Moderate; C = Optional
Rating of Evidence: I = data from randomized controlled trials; II = data from well-designed nonrandomized trials or observational cohort studies with long-term clinical outcomes; III = expert opinion

Virologic Definitions

Virologic suppression: A confirmed HIV RNA level below the limit of assay detection (e.g., <48 copies/mL).

Virologic failure: The inability to achieve or maintain suppression of viral replication (to an HIV RNA level <200 copies/mL).

Incomplete virologic response: Two consecutive plasma HIV RNA levels >200 copies/mL after 24 weeks on an ARV regimen. Baseline HIV RNA may affect the time course of response, and some regimens will take longer than others to suppress HIV RNA levels.

Virologic rebound: Confirmed detectable HIV RNA (to >200 copies/mL) after virologic suppression.

Persistent low-level viremia: Confirmed detectable HIV RNA levels that are <1,000 copies/mL.

Virologic blip: After virologic suppression, an isolated detectable HIV RNA level that is followed by a return to virologic suppression.

Causes of Virologic Failure

Virologic failure in a patient can occur for multiple reasons. Data from older patient cohorts suggested that suboptimal adherence and drug intolerance/toxicity accounted for 28%–40% of virologic failure and regimen discontinuations *[1-2]*. More recent data suggest that most virologic failure on first-line regimens occurred due to either pre-existing (transmitted) drug resistance or suboptimal adherence *[3]*. Factors associated with virologic failure include:

- Patient characteristics
  - higher pretreatment or baseline HIV RNA level (depending on the specific regimen used)
  - lower pretreatment or nadir CD4 T-cell count
  - prior AIDS diagnosis
  - comorbidities (e.g., active substance abuse, depression)
  - presence of drug-resistant virus, either transmitted or acquired
  - prior treatment failure
  - incomplete medication adherence and missed clinic appointments

- ARV regimen characteristics
  - drug side effects and toxicities
  - suboptimal pharmacokinetics (variable absorption, metabolism, or, theoretically, penetration into reservoirs)
  - food/fasting requirements
  - adverse drug-drug interactions with concomitant medications
  - suboptimal virologic potency
  - prescription errors

- Provider characteristics, such as experience in treating HIV disease

- Other or unknown reasons

Management of Patients with Virologic Failure

Assessment of Virologic Failure

If virologic failure is suspected or confirmed, a thorough work-up is indicated, addressing the following factors:
- change in HIV RNA and CD4 T-cell counts over time
- occurrence of HIV-related clinical events
- ARV treatment history
- results of prior resistance testing (if any)
- medication-taking behavior (including adherence to recommended drug doses, dosing frequency, and food/fasting requirements)
- tolerability of medications
- concomitant medications and supplements (with consideration for adverse drug-drug interactions)
- comorbidities (including substance abuse)

In many cases, the cause(s) of virologic failure will be identified. In some cases, no obvious cause(s) may be identified. It is important to distinguish among the reasons for virologic failure because the approaches to subsequent therapy differ. The following potential causes of virologic failure should be explored in depth.

- **Adherence.** Assess the patient's adherence to the regimen. For incomplete adherence, identify and address the underlying cause(s) (e.g., difficulties accessing or tolerating medications, depression, active substance abuse) and

simplify the regimen if possible (e.g., decrease pill count or dosing frequency). (See **Adherence**.)

- **Medication Intolerance.** Assess the patient's tolerance of the current regimen and the severity and duration of side effects, keeping in mind that even minor side effects can impact adherence. Management strategies for intolerance in the absence of drug resistance may include:
  - using symptomatic treatment (e.g., antiemetics, antidiarrheals)
  - changing one ARV to another within the same drug class, if needed (e.g., change to tenofovir [TDF] or abacavir [ABC] for zidovudine [ZDV]-related toxicities; change to nevirapine [NVP] or etravirine [ETR] for efavirenz [EFV]-related toxicities) *[4-5]*
  - changing from one drug class to another (e.g., from a non-nucleoside reverse transcriptase inhibitor [NNRTI] to a protease inhibitor [PI], from enfuvirtide [T-20] to raltegravir [RAL]) if necessary and no prior drug resistance is suspected

- **Pharmacokinetic Issues.** Review food/fasting requirements for each medication. Review recent history of gastrointestinal symptoms (such as vomiting or diarrhea) to assess the likelihood of short-term malabsorption. Review concomitant medications and dietary supplements for possible adverse drug-drug interactions (consult **Drug Interactions** section and tables for common interactions) and make appropriate substitutions for ARV agents and/or concomitant medications, if possible. Therapeutic drug monitoring (TDM) may be helpful if pharmacokinetic drug-drug interactions or impaired drug absorption leading to decreased ARV exposure is suspected. (See also **Exposure-Response Relationship and Therapeutic Drug Monitoring**.)

- **Suspected Drug Resistance.** Obtain resistance testing while the patient is taking the failing regimen or within 4 weeks after regimen discontinuation if the plasma HIV RNA level is >500 copies/mL **(AII)**. (See **Drug-Resistance Testing**.) Evaluate the degree of drug resistance and consider the patient's prior treatment history and prior resistance test results. Drug resistance tends to be cumulative for a given individual; thus, all prior treatment history and resistance test results should be taken into account. Routine genotypic or phenotypic testing gives information relevant for selecting nucleoside reverse transcriptase inhibitors (NRTIs), NNRTIs, and PIs. Additional drug-resistance tests for patients experiencing failure on fusion inhibitors and/or integrase strand transfer inhibitors (INSTIs) and viral tropism tests for patients experiencing failure on a CCR5 antagonist also are available. (See **Drug-Resistance Testing**.)

Changing ART

There is no consensus on the optimal time to change therapy for virologic failure. The goal of ART is to suppress HIV replication to a level where drug-resistance mutations do not emerge. However, the specific level of viral suppression needed to achieve durable virologic suppression remains unknown. Selection of drug resistance does not appear to occur in patients with persistent HIV RNA levels suppressed to <48 copies/mL *[6]*, although this remains controversial *[7]*.

The clinical implications of HIV RNA in the range of >48 to <200 copies/mL in a patient on ART are controversial. Unlike the case with higher levels of HIV RNA, most, if not all, circulating virus from individuals with this level of HIV RNA results from the release of HIV from long-lived latently infected cells and does not signify ongoing viral replication with the emergence of drug-resistant virus *[8]*. Although some studies have suggested that viremia at this low level predicts subsequent failure *[9]* and can be associated with the evolution of drug resistance *[10]*, a large retrospective analysis showed that using an HIV RNA threshold for virologic failure of <200 copies/mL had the same predictive value as using a threshold of <50 copies/mL *[11]*.

Newer technologies (e.g., Taqman assay) have made it possible to detect HIV RNA in more patients with low level viremia (<200 copies/mL) than was possible with previous assays. Use of these newer assays has resulted in more confirmatory viral load testing than may be necessary *[12-14]*.

Persistent HIV RNA levels >200 copies/mL often are associated with evidence of viral evolution and drug-resistance mutation accumulation *[15]*; this is particularly common when HIV RNA levels are >500 copies/mL *[16]*. Persistent plasma HIV RNA levels in the 200 to 1,000 copies/mL range should therefore be considered as virologic failure.

Viremia "blips" (e.g., viral suppression followed by a detectable HIV RNA level and then subsequent return to undetectable levels) usually are not associated with subsequent virologic failure *[17]*.

Management of Virologic Failure

Once virologic failure is confirmed, generally the regimen should be changed as soon as possible to avoid progressive accumulation of resistance mutations *[18]*.

Ideally, a new ARV regimen should contain at least two, and preferably three, fully active drugs on the basis of drug treatment history, resistance testing, or new mechanistic class **(AI)** *[19-27]*. Some ARV drugs (e.g., NRTIs) may contribute partial ARV activity to a regimen, despite drug resistance *[28]*, while others (e.g., T-20, NNRTIs, RAL) likely do not provide partial activity *[28-30]*. Because of the potential for drug-class cross resistance that reduces drug activity, using a "new" drug that a patient has not yet taken may not mean that the drug is fully active. In addition, archived drug-resistance mutations may not be detected by standard drug-resistance tests, emphasizing the importance of considering treatment history and prior drug-resistance tests. Drug potency and viral susceptibility are more important than the number of drugs prescribed.

Early studies of ART-experienced patients identified factors associated with better virologic responses to subsequent regimens *[31-32]*. These factors included lower HIV RNA level and/or higher CD4 cell count at the time of therapy change, using a new (i.e., not yet taken) class of ARV drugs, and using ritonavir (RTV)-boosted PIs in PI-experienced patients.

More recent clinical trials support the strategy of conducting reverse transcriptase (RT) and protease (PT) resistance testing (both genotype and phenotype) while an ART-experienced patient is taking a failing ARV regimen, designing a new regimen based on the treatment history and resistance testing results, and selecting at least two and preferably three active drugs for the new treatment regimen *[20-21, 23-24, 33]*. Higher genotypic and/or phenotypic susceptibility scores (quantitative measures of drug activity) are associated with better virologic responses *[23-24]*. Patients who receive more active drugs have a better and more prolonged virologic response than those with fewer active drugs in the regimen. Active ARV drugs include those with activity against drug-resistant viral strains, including newer members of existing classes (the NNRTI—ETR, the PIs—darunavir [DRV] and tipranavir [TPV]) and drugs with new mechanisms of action (the fusion inhibitor—T-20, the CCR5 antagonist—maraviroc [MVC] in patients with R5 but not X4 virus, and the INSTI—RAL). Drug-resistance tests for patients experiencing failure on fusion inhibitors (FIs) and/or INSTIs and viral tropism tests for patients experiencing failure on a CCR5 antagonist also are available. (See **Drug-Resistance Testing**.)

Clinical Scenarios of Virologic Failure

- ***Low-level viremia (HIV RNA <1,000 copies/mL).*** Assess adherence. Consider variability in HIV RNA assays. Patients with HIV RNA <48 copies/mL or isolated increases in HIV RNA ("blips") do not require a change in treatment *[13]* **(AII)**. There is no consensus regarding how to manage patients with HIV RNA levels >48 copies/mL and <200 copies/mL; HIV RNA levels should be followed over time to assess the need for changes (**AIII**). Patients with persistent HIV RNA levels >200 copies/mL often select out drug-resistant viral variants, particularly when HIV RNA levels are >500 copies/mL. Persistent plasma HIV RNA levels in the 200 to 1,000 copies/mL range should be considered as possible virologic failure; resistance testing should be attempted if the HIV RNA level is >500 copies/mL. For individuals with sufficient therapeutic options, consider treatment change **(BIII)**.

- ***Repeated detectable viremia (HIV RNA >1,000 copies/mL) and NO drug resistance identified.*** Consider the timing of the drug-resistance test (e.g., was the patient off ARV for >4 weeks and/or nonadherent?). Consider resuming the same regimen or starting a new regimen and then repeating genotypic testing early (e.g., in 2–4 weeks) to determine whether a resistant viral strain emerges **(CIII)**.

- ***Repeated detectable viremia (HIV RNA >1,000 copies/mL) and drug resistance identified.*** The goals in this situation are to resuppress HIV RNA levels maximally (i.e., to <48 copies/mL) and to prevent further selection of resistance mutations. With the availability of multiple new ARVs, including some with new mechanisms of action, this goal is now possible in many patients, including those with extensive treatment experience and drug resistance. With virologic failure, consider changing the treatment regimen sooner, rather than later, to minimize continued selection of resistance mutations. In a patient with ongoing viremia and evidence of resistance, some drugs in a regimen (e.g., NNRTI, T-20, RAL) should be discontinued promptly to decrease the risk of selecting additional drug-resistance mutations in order to preserve the activity of these drug classes in future regimens. A new regimen should include at least two, and preferably three, fully active agents **(AII)**.

- ***Highly drug resistant HIV.*** There is a subset of patients who have experienced toxicity and/or developed resistance to all or most currently available regimens, and designing a regimen with two or three fully active drugs is not possible. Many of these patients received suboptimal ARV regimens (i.e., did not have access to more than one or two of the drugs at the time they became available) or have been unable to adhere to any regimen. If maximal virologic suppression cannot be achieved, the goals are to preserve immunologic function and to prevent clinical progression (even with ongoing viremia). There is no consensus on how to optimize the management of these patients. It is reasonable to observe a patient on the same regimen, rather than changing the regimen, depending on the stage of HIV disease **(BII)**. Even partial virologic suppression of HIV RNA >0.5 $\log_{10}$ copies/mL from baseline correlates with clinical benefits *[34]*. There is evidence from cohort studies that continuing therapy, even in the presence of viremia and the absence of CD4 T-cell count increases, reduces the risk of disease progression *[35]*. Other cohort studies suggest continued immunologic and clinical benefits if the HIV RNA level is maintained <10,000–20,000 copies/mL *[36-37]*. However, these potential benefits all must be balanced with the ongoing risk of accumulating additional resistance mutations.

  In general, adding a single, fully active ARV in a new regimen is **not** recommended because of the risk of rapid development of resistance **(BII)**. However, in patients with a high likelihood of clinical progression (e.g., CD4 cell count <100 cells/mm^3) and limited drug options, adding a single drug may reduce the risk of immediate clinical progression, because even transient decreases in HIV RNA and/or transient increases in CD4 cell counts have been associated with clinical benefits **(CI)**. Weighing the risks (e.g., selection of drug resistance) and benefits (e.g., ARV activity) of using a single active drug in the heavily ART experienced patient is complicated, and consultation with an expert is advised.

  Patients with ongoing viremia and with an insufficient number of approved treatment options to construct a fully suppressive regimen may be candidates for research studies or expanded access programs, or single-patient access of investigational new drug(s) (IND), as specified in Food and Drug Administration (FDA) regulations: **http://www.fda.gov/AboutFDA/CentersOffices/CDER/ucm163982.htm**).

  Discontinuing or briefly interrupting therapy in a patient with viremia may lead to a rapid increase in HIV RNA and a decrease in CD4 T-cell count and increases the risk of clinical progression *[38-39]*. Therefore, this strategy is **not** recommended **(AI)**. See **Discontinuation or Interruption of Antiretroviral Therapy**.

- ***Prior treatment and suspected drug resistance, now presenting to care in need of therapy with limited information (i.e., incomplete or absence of self-reported history, medical records, or previous resistance data).*** Every effort should be made to obtain medical records and prior drug-resistance testing results; however, this is not always possible. One strategy is to restart the most recent ARV regimen and assess drug resistance in 2–4 weeks to help guide the choice of the next regimen; another strategy is to start two or three drugs known to be active based on treatment history (e.g., MVC with R5 virus, RAL if no prior INSTI).

Immunologic Failure: Definition, Causes, and Management

Immunologic failure can be defined as the failure to achieve and maintain an adequate CD4 response despite virologic suppression. Increases in CD4 counts in ARV-naïve patients with initial ARV regimens are approximately 150 cells/mm^3 over the first year *[40]*. A CD4 count plateau may occur after 4–6 years of treatment with suppressed viremia *[41-45]*.

No accepted specific definition for immunologic failure exists, although some studies have focused on patients who fail to increase CD4 counts above a specific threshold (e.g., >350 or 500 cells/mm^3) over a specific period of time (e.g., 4–7 years). Others have focused on an inability to increase CD4 counts above pretherapy levels by a certain threshold (e.g., >50 or 100 cells/mm^3) over a given time period. The former criterion may be preferable because of data linking these thresholds with the risk of non-AIDS clinical events *[46]*.

The proportion of patients experiencing immunologic failure depends on how failure is defined, the observation period, and the CD4 count when treatment was started. In the longest study conducted to date, the percentage of patients with suppressed viremia who reached a CD4 count >500 cells/mm^3 through 6 years of treatment was 42% in those starting treatment with a CD4 count <200 cells/mm^3, 66% in those starting with a CD4 count 200–350 cells/mm^3, and 85% in those starting with a CD4 count >350 cells/mm^3 *[41]*.

A persistently low CD4 count while on suppressive ART is associated with a small, but appreciable, risk of AIDS- and non-AIDS-related morbidity and mortality *[47-48]*. For example, in the FIRST study *[49]*, a low CD4 count on therapy was associated with an increased risk of AIDS-related complications (adjusted hazard ratio of 0.56 per 100 cells/mm^3 higher CD4 count). Similarly, a low CD4 count was associated with an increased risk of non-AIDS events, including cardiovascular, hepatic, and renal disease and cancer. Other studies support these associations *[50-53]*.

Factors associated with poor CD4 T-cell response:
- CD4 count <200/mm^3 when starting ART
- Older age
- Coinfection (e.g., hepatitis C virus [HCV], HIV-2, human T-cell leukemia virus type 1 [HTLV-1], HTLV-2)
- Medications, both ARVs (e.g., ZDV *[54]*, TDF + didanosine [ddI] *[55-57]*) and other medications.
- Persistent immune activation
- Loss of regenerative potential of the immune system
- Other medical conditions

Assessment of Immunologic Failure. CD4 count should be confirmed by repeat testing. Concomitant medications should be reviewed carefully, with a focus on those known to decrease white blood cells or, specifically, CD4 T-cells (e.g., cancer chemotherapy, interferon, prednisone, ZDV; combination of TDF and ddI), and consideration should be given to substituting or discontinuing these drugs, if possible. Untreated coinfections (e.g., HIV-2, HTLV-1, HTLV-2) and serious medical conditions (e.g., malignancy) also should be considered. In many cases, no obvious cause for immunologic failure can be identified.

Management of Immunologic Failure. No consensus exists on when or how to treat immunologic failure. Given the risk of clinical events, it is reasonable to focus on patients with CD4 counts <200 cells/mm^3 because patients with higher CD4 counts have a lower risk of clinical events. It is not clear that immunologic failure in the setting of virologic suppression should prompt a change in the ARV regimen. Because ongoing immune activation occurs in some patients with suppressed HIV RNA levels, some have suggested adding a drug to an existing regimen. However, this strategy does not result in clear virologic or immunologic benefit *[58]*. Others suggest changing the regimen to another regimen (e.g., from NNRTI-based to PI-based, INSTI-based, or CCR5 antagonist-based regimens), but this strategy has not shown clear benefit.

An immune-based therapy, interleukin-2, demonstrated CD4 count increases but no clinical benefit in two large randomized studies *[59]* and therefore is not recommended **(AI)**. Other immune-based therapies (e.g., gene therapies, growth hormone, cyclosporine, interleukin-7) are under investigation. Currently, immune-based therapies **should not** be used unless in the context of a clinical trial **(AIII)**.

REGIMEN SIMPLIFICATION (Updated January 10, 2011)

Regimen simplification can be defined broadly as a change in established effective therapy to reduce pill burden and dosing frequency, to enhance tolerability, or to decrease specific food and fluid requirements. Many patients on suppressive antiretroviral therapy (ART) may be considered candidates for regimen simplification, especially if (1) they are receiving treatments that are no longer recommended as preferred or alternative choices for initial therapy; (2) they were prescribed a regimen in the setting of treatment failure at a time when there was an incomplete understanding of resistance or drug-drug interaction data; or (3) they were prescribed a regimen prior to the availability of newer options or formulations that might be easier to administer and/or more tolerable.

This section will review situations in which clinicians might consider simplifying treatment in a patient with virologic suppression. Importantly, this section will not review consideration of changes in treatment for reducing ongoing adverse effects. Regimens used in simplification strategies generally should be those that have proven high efficacy in antiretroviral (ARV)-naïve patients (see **What to Start**) or that would be predicted to be highly active for a given patient based on the individual's past treatment history and resistance profile.

Rationale

The major rationales behind regimen simplification are to improve the patient's quality of life, maintain long-term adherence, avoid toxicities that may develop with prolonged ARV use, and reduce the risk of virologic failure. Systematic reviews in the non-HIV literature have shown that adherence is inversely related to the number of daily doses *[1]*. Some prospective studies in HIV-infected individuals have shown that those on regimens with reduced dosing frequency have higher levels of adherence *[2-3]*. Patient satisfaction with regimens that contain fewer pills and reduced dosing frequency is also higher *[4]*.

Candidates for Regimen Simplification

Unlike ARV agents developed earlier in the HIV epidemic, many ARV medications approved in recent years have sufficiently long half-lives to allow for once-daily dosing, and most also do not have dietary restrictions. Patients on regimens initiated earlier in the era of potent combination ART with drugs that pose a high pill burden and/or frequent dosing requirements are often good candidates for regimen simplification.

Patients without suspected drug-resistant virus. Patients on first (or modified) treatment regimens without a history of treatment failure are ideal candidates for regimen simplification. These patients are less likely to harbor drug-resistant virus, especially if a pretreatment genotype did not detect drug resistance. Prospective clinical studies have demonstrated that the likelihood of treatment failure is relatively low in patients after simplification and, indeed, may be lower than in patients who do not simplify treatment *[5]*. However, some patients may have unrecognized drug-resistant HIV, either acquired at the time of infection or as a consequence of prior treatment, such as patients who were treated with presumably nonsuppressive mono- or dual-nucleoside reverse transcriptase inhibitor (NRTI) regimens before the widespread availability of HIV RNA monitoring and resistance testing.

Patients with documented or suspected drug resistance. Treatment simplification may also be appropriate for selected individuals who achieve viral suppression after having had documented or suspected drug resistance. Often, these patients are on regimens selected when management of drug resistance, understanding of potentially adverse drug-drug interactions, and understanding of treatment options were relatively limited. Regimen simplification may also be considered for patients on two ritonavir (RTV)-boosted protease inhibitors (PIs). Although successful in suppressing viral replication, this treatment may cause patients to be on regimens that are cumbersome, costly, and associated with potential long-term adverse events. The ability to simplify regimens in this setting often reflects the availability of recently approved agents that have activity against drug-resistant virus and are easier to take without sacrificing ARV activity. Specific situations in which drug simplification could be considered in ART-experienced patients with viral drug resistance are outlined below. Simplifying regimens in patients who have extensive prior treatment histories is complicated. In such a case, a patient's treatment history, treatment responses and tolerance, and resistance test results should be thoroughly reviewed before designing a new regimen. Expert consultation should be considered whenever possible.

Types of Treatment Simplification

Within-Class Simplifications. Within-class substitutions offer the advantage of not exposing patients to still-unused drug classes, which potentially preserves other classes for future regimens. In general, within-class substitutions use a newer agent; coformulated drugs; or a formulation that has a lower pill burden, a lower dosing frequency, or would be less likely to cause toxicity.

- ***NRTI Substitutions*** *(e.g., changing from zidovudine [ZDV] or stavudine [d4T] to tenofovir [TDF] or abacavir [ABC])**:*** This may be considered for a patient who has no history of viral resistance on an NRTI-containing regimen. Other NRTIs may be substituted to create a regimen with lower dosing frequency (e.g., once daily) that takes advantage of coformulated agents and potentially avoids some long-term toxicities (e.g., pancreatitis, peripheral neuropathy, lipoatrophy).
- ***Switching of Non-Nucleoside Reverse Transcriptase Inhibitors (NNRTIs)*** *(e.g., from nevirapine [NVP] to efavirenz [EFV])**:*** This may be considered to reduce dosing frequency or to take advantage of coformulated agents.
- ***Switching of PIs:*** This switch can be from one PI to another PI, to the same PI at a lower dosing frequency (such as from twice-daily to once-daily RTV-boosted lopinavir [LPV/r] or RTV-boosted darunavir [DRV/r]) or, in the case of atazanavir (ATV), to administration without RTV boosting *[6]*. (Unboosted ATV is presently not a preferred PI component and not recommended if the patient is taking TDF or if the patient has HIV with reduced susceptibility to ATV.) Such changes can reduce dosing frequency, pill count, drug-drug or drug-food interactions, or dyslipidemia or can take advantage of coformulation. These switches can be done with relative ease in patients without PI-resistant virus. However, these switches are not recommended in patients who have a history of documented or suspected PI resistance because convincing data in this setting are lacking.

Out-of-Class Substitutions. One common out-of-class substitution for regimen simplification involves a change from a PI-based to an NNRTI-based regimen. An important study in this regard was the NEFA trial, which evaluated substitution of a PI-based regimen in virologically suppressed patients with NVP, EFV, or ABC *[7]*. Although the baseline regimens in the study are no longer in widespread use, the NEFA findings are still relevant and provide information about the risks and benefits of switching treatment in patients with virologic suppression. In this study, 460 patients on stable, PI-based regimens with virologic suppression (<200 copies/mL for the previous 6 months) were switched to their randomized treatment arms. After 36 months of follow-up, virologic failure occurred more frequently in patients switched to ABC than in patients switched to EFV or NVP. The increased risk of treatment failure was particularly high in patients who had previous suboptimal treatment with mono- and dual-NRTI therapy. This emphasizes the need to consider the potential for drug-resistant virus prior to attempting simplification *[8]*.

Newer agents that target different sites in the HIV life cycle, such as the integrase strand transfer inhibitor (INSTI) raltegravir (RAL) and the CCR5 antagonist maraviroc (MVC), also offer opportunities for out-of-class substitutions, particularly in patients who have a history of virus resistant to older HIV drugs. Three randomized studies have evaluated replacing a boosted PI with RAL in virologically suppressed patients. In two of these studies *[9-10]*, the switch to RAL was associated with an increased risk of virologic failure in patients with documented or suspected pre-existing NRTI resistance; a third study did not find this higher risk, possibly due to a longer period of virologic suppression before the change *[11]*. Overall, these results suggest that in ART-experienced patients, RAL should be used with caution as a substitute for a boosted PI. This strategy should be avoided in patients with documented NRTI resistance unless there are other fully active drugs in the regimen.

Because enfuvirtide (T-20) requires twice-daily injections, causes injection-site reactions, and is more expensive than other available ARV agents, patients who are virologically suppressed on T-20-containing regimens may wish to substitute T-20 with an active oral agent. Because the majority of patients on T-20 have highly drug-resistant virus, substitution must be with another fully active agent. Data from one randomized trial and one observational study suggest that RAL can safely substitute for T-20 in patients not previously treated with INSTI *[12-13]*. Although this strategy generally maintains virologic suppression and is well tolerated, clinicians should be aware that any drug substitution may introduce unanticipated adverse effects or drug-drug interactions *[14]*.

Other newer agents that might be considered as substitutes for T-20 are etravirine (ETR) or MVC. Use of ETR in this setting would optimally be considered only when viral susceptibility to ETR can be assured from resistance testing performed prior to virologic suppression and after carefully assessing for possible deleterious drug-drug interactions

(e.g., ETR cannot be administered with several PIs [see **Table 16b**]). In the ETR early access program, switching from T-20 to ETR showed promise in maintaining viral suppression at 24 weeks, but only 37 subjects were included in this report *[15]*. MVC is only active in those with documented R5-only virus, a determination that cannot routinely be made in those with undetectable HIV RNA on a stable regimen. Although there is a commercially available proviral DNA assay to assess viral tropism in virologically suppressed patients, there are no clinical data on whether results of this test predict the successful use of MVC as a substitute for another active drug.

Reducing the number of active drugs in a regimen. This approach to treatment simplification involves switching a patient from a suppressive regimen to fewer active drugs. In early studies, this approach was associated with a higher risk of treatment failure than continuation of standard treatment with two NRTIs plus a PI *[16]*. More recently, studies have evaluated the use of an RTV-boosted PI as monotherapy after virologic suppression with a two-NRTI + boosted-PI regimen *[17-18]*. The major motivations for this approach are a reduction in NRTI-related toxicity and lower cost. In a randomized clinical trial *[18]*, low-level viremia was more common in those on maintenance LPV/r alone than on a three-drug combination regimen. Viral suppression was achieved by resuming the NRTIs. Studies of DRV/r monotherapy, both as once- or twice-daily dosing, have reported mixed results *[19-20]*. In aggregate, boosted-PI monotherapy as initial *[21]* or as simplification treatment has been somewhat less effective in achieving complete virologic suppression and avoiding resistance. Therefore, this strategy cannot be recommended outside of a clinical trial.

Monitoring After Treatment Simplification

Patients should be evaluated 2–6 weeks after treatment simplification to assess tolerance and to undergo laboratory monitoring, including HIV RNA, CD4 cell count, and markers of renal and liver function. Assessment of fasting cholesterol subsets and triglycerides should be performed within 3 months after the change in therapy. In the absence of any specific complaints, laboratory abnormalities, or viral rebound at that visit, patients may resume regularly scheduled clinical and laboratory monitoring.

EXPOSURE-RESPONSE RELATIONSHIP AND THERAPEUTIC DRUG MONITORING (TDM) FOR ANTIRETROVIRAL AGENTS (Updated January 10, 2011)

Panel's Recommendations:

- ***Therapeutic drug monitoring (TDM) for antiretroviral (ARV) agents is not recommended for routine use in the management of the HIV-infected adult (CIII).***
- ***TDM may be considered in selected clinical scenarios, as discussed in the text below.***

Rating of Recommendations: A = Strong; B = Moderate; C = Optional
Rating of Evidence: I = data from randomized controlled trials; II = data from well-designed nonrandomized trials or observational cohort studies with long-term clinical outcomes; III = expert opinion

Knowledge of the relationship between systemic exposure (or concentration) and drug responses (beneficial and/or adverse) is key in selecting the dose of a drug, in understanding the variability in the response of patients to a drug, and in designing strategies to optimize response and tolerability.

TDM is a strategy applied to certain antiarrhythmics, anticonvulsants, antineoplastics, and antibiotics that utilizes measured drug concentrations to design dosing regimens to improve the likelihood of the desired therapeutic and safety outcomes. The key characteristic of a drug that is a candidate for TDM is knowledge of the exposure-response relationship and a therapeutic range of concentrations. The therapeutic range is a range of concentrations established through clinical investigations that are associated with a greater likelihood of achieving the desired therapeutic response and/or reducing the frequency of drug-associated adverse reactions.

Several ARV agents meet most of the characteristics of agents that can be considered candidates for a TDM strategy *[1]*. The rationale for TDM in managing antiretroviral therapy (ART) derives from the following:

- data showing that considerable interpatient variability in drug concentrations exists among patients who take the same dose;
- data indicating that relationships exist between the concentration of drug in the body and anti-HIV effect and, in some cases, toxicities; and
- data from small prospective studies demonstrating that TDM improved virologic response and/or decreased the incidence of concentration-related drug toxicities *[2-3]*.

TDM for ARV agents, however, is not recommended for routine use in the management of the HIV-infected adult (CIII).

Multiple factors limit the routine use of TDM in HIV-infected adults *[4-5]*. These factors include:

- lack of large prospective studies demonstrating that TDM improves clinical and virologic outcomes. (This is the most important limiting factor for the implementation of TDM at present.);
- lack of established therapeutic range of concentrations for all ARV drugs that is associated with achieving the desired therapeutic response and/or reducing the frequency of drug-associated adverse reactions;
- intrapatient variability in ARV drug concentrations;
- lack of widespread availability of clinical laboratories that perform quantitation of ARV concentrations under rigorous quality assurance/quality control standards; and
- shortage of experts to assist with interpretation of ARV concentration data and application of such data to revise patients' dosing regimens.

Exposure-Response Relationships and TDM with Different ARV Classes

Protease Inhibitors (PIs), Non-Nucleoside Reverse Transcriptase Inhibitors (NNRTIs), and Integrase Inhibitors. Relationships between the systemic exposure to PIs and NNRTIs and treatment response have been reviewed in various publications *[4-7]*. Although there are limitations and unanswered questions, the consensus among clinical pharmacologists from the United States and Europe is that the data provide a framework for the potential implementation of TDM for PIs and NNRTIs. However, information on relationships between concentrations and drug-associated toxicities are sparse. Clinicians who use TDM as a strategy to manage either ARV response or toxicities should consult the most current data on the proposed therapeutic concentration range. Exposure-response data for darunavir (DRV), etravirine (ETR), and raltegravir (RAL) are accumulating but are not sufficient to recommend minimum trough concentrations. The median trough concentrations for these agents in HIV-infected persons receiving the recommended dose are included in **Table 9b**.

CCR5 Antagonists. Trough maraviroc (MVC) concentrations have been shown to be an important predictor of virologic success in studies conducted in ART-experienced persons *[8-9]*. Clinical experience in the use of TDM for MVC, however, is very limited. Nonetheless, as with PIs and NNRTIs, the exposure-response data provide a framework for TDM, and that information is presented in these guidelines (**Table 9b**).

Nucleoside Reverse Transcriptase Inhibitors (NRTIs). Relationships between plasma concentrations of NRTIs and their intracellular pharmacologically active moieties have not yet been established. Therefore, monitoring of plasma or intracellular NRTI concentrations for an individual patient largely remains a research tool. Measurement of plasma concentrations, however, is routinely used for studies of drug-drug interactions.

Scenarios for Use of TDM. Multiple scenarios exist in which both ARV concentration data and expert opinion may be useful in patient management. Consultation with a clinical pharmacologist or a clinical pharmacist with HIV expertise may be advisable in these cases. These scenarios include the following:

- **Suspect clinically significant drug-drug or drug-food interactions** that may result in reduced efficacy or increased dose-related toxicities;
- **Changes in pathophysiologic states** that may impair gastrointestinal, hepatic, or renal function, thereby potentially altering drug absorption, distribution, metabolism, or elimination;
- **Pregnant women** who may be at risk of virologic failure as a result of changes in their pharmacokinetic parameters during the later stage of pregnancy, which may result in plasma concentrations lower than those achieved in the earlier stages of pregnancy and in the nonpregnant patient;
- **Heavily pretreated patients** experiencing virologic failure and who may have viral isolates with reduced susceptibility to ARVs;
- **Use of alternative dosing regimens and ARV combinations** for which safety and efficacy have not been established in clinical trials;
- **Concentration-dependent, drug-associated toxicities**; and
- **Lack of expected virologic response** in medication-adherent persons.

TDM

- **For patients who have drug-susceptible virus**. **Table 9a** includes a synthesis of recommendations *[2-7]* for minimum target trough PI and NNRTI concentrations in persons with drug-susceptible virus.
- **For ART-experienced patients with virologic failure (see Table 9b)**. Fewer data are available to formulate suggestions for minimum target trough concentrations in ART-experienced patients who have viral isolates with reduced susceptibility to ARV agents. Concentration recommendations for tipranavir (TPV) and MVC were derived only from studies in ART-experienced persons. It is likely that use of PIs and NNRTIs in the setting of reduced viral susceptibility may require higher trough concentrations than those needed for wild-type virus. The inhibitory quotient (IQ), which is the ratio of ARV drug concentration to a measure of susceptibility (genotype or phenotype) of the patient's strain of HIV to that drug, may additionally improve prediction of virologic response—as has been shown, for example, with DRV in ART-experienced persons *[10-11]*. Exposure-response data for DRV, ETR, and RAL are accumulating but are not sufficient to recommend minimum trough concentrations. The median trough concentrations for these agents in HIV-infected persons receiving the recommended dose are included in **Table 9b**.

Using Drug Concentrations to Guide Therapy. There are several challenges and considerations for implementation of TDM in the clinical setting. Use of TDM to monitor ARV concentrations in a patient requires multiple steps:

- quantification of the concentration of the drug, usually in plasma or serum;
- determination of the patient's pharmacokinetic characteristics;
- integration of information on patient adherence;
- interpretation of the concentrations; and
- adjustment of the drug dose to achieve concentrations within the therapeutic range, if necessary.

Guidelines for the collection of blood samples and other practical suggestions can be found in a position paper by the Adult AIDS Clinical Trials Group Pharmacology Committee *[4]*.

A final caveat to the use of measured drug concentrations in patient management is a general one—drug concentration information cannot be used alone; it must be integrated with other clinical information. In addition, as knowledge of associations between ARV concentrations and virologic response continues to accumulate, clinicians who employ a TDM strategy for patient management should consult the most current literature.

Table 9a. Trough Concentrations of Antiretroviral Drugs for Patients Who Have Drug-Susceptible Virus **(Updated January 10, 2011)**

Drug	Concentration (ng/mL)
Suggested minimum target trough concentrations in patients with HIV-1 susceptible to the ARV drugs *[2-9]*	
Fosamprenavir (FPV)	400 (measured as amprenavir concentration)
Atazanavir (ATV)	150
Indinavir (IDV)	100
Lopinavir (LPV)	1,000
Nelfinavir[1] (NFV)	800
Saquinavir (SQV)	100–250
Efavirenz (EFV)	1,000
Nevirapine (NVP)	3,000

[1]Measurable active (M8) metabolite

Table 9b. Trough Concentrations of Antiretroviral Drugs for Treatment-Experienced Patients with Virologic Failure (Updated January 10, 2011)

Drug	Concentration (ng/mL)
Suggested minimum target trough concentrations for ART-experienced patients who have resistant HIV-1 strains	
Maraviroc (MVC)	>50
Tipranavir (TPV)	20,500
Median (Range) Trough Concentrations from Clinical Trials *[12-14]*	
Darunavir (DRV) (600 mg twice daily)	3,300 (1,255–7,368)
Etravirine (ETR)	275 (81–2,980)
Raltegravir (RAL)	72 (29–118)

DISCONTINUATION OR INTERRUPTION OF ANTIRETROVIRAL THERAPY

(Updated November 3, 2008)

Discontinuation of antiretroviral therapy (ART) may result in viral rebound, immune decompensation, and clinical progression. Unplanned interruption of ART may become necessary because of severe drug toxicity, intervening illness, surgery that precludes oral therapy, or unavailability of antiretroviral (ARV) medication. Some investigators have studied planned treatment discontinuation strategies in situations or for reasons that include: in patients who achieve viral suppression and wish to enhance adherence; to reduce inconvenience, long-term toxicities, and costs for patients; or in extensively treated patients who experience treatment failure due to resistant HIV, to allow reversion to wild-type virus. Potential risks and benefits of interruption vary according to a number of factors, including the clinical and immunologic status of the patient, the reason for the interruption, the type and duration of the interruption, and the presence or absence of resistant HIV at the time of interruption. Below are brief discussions on what is currently known about the risks and benefits of treatment interruption in some of these circumstances.

Short-Term Therapy Interruptions

Reasons for short-term interruption (days to weeks) of ART vary and may include drug toxicity; intercurrent illnesses that preclude oral intake, such as gastroenteritis or pancreatitis; surgical procedures; or unavailability of drugs. Stopping ARV drugs for a short time (i.e., <1 to 2 days) due to medical/surgical procedures can usually be done by holding all drugs in the regimen. Recommendations for some other scenarios are listed below:

Unanticipated Need for Short-Term Interruption

- **When a patient experiences a severe or life-threatening toxicity or unexpected inability to take oral medications**—all components of the drug regimen should be stopped simultaneously, regardless of drug half-life.

Planned Short Term Interruption (>2–3 days)

- **When all regimen components have similar half-lives and do not require food for proper absorption**—all drugs may be given with a sip of water, if allowed; otherwise, all drugs should be stopped simultaneously. All discontinued regimen components should be restarted simultaneously.
- **When all regimen components have similar half-lives and require food for adequate absorption, and the patient cannot take anything by mouth for a sustained period of time**—temporary discontinuation of all drug components is indicated. The regimen should be restarted as soon as the patient can resume oral intake.
- **When the ARV regimen contains drugs with differing half-lives**—stopping all drugs simultaneously may result in functional monotherapy with the drug with the longest half-life (typically a non-nucleoside reverse transcriptase inhibitor [NNRTI]). Options in this circumstance are discussed below. (See **Discontinuation of efavirenz, etravirine, or nevirapine**.)

Interruption of Therapy after Pregnancy

ARV drugs for prevention of perinatal transmission of HIV are recommended for all pregnant women, regardless of whether they have indications for ART for their own health. Following delivery, considerations regarding continuation of the ARV regimen for maternal therapeutic indications are the same as for other nonpregnant individuals. The decision of whether to continue therapy after delivery should take into account current recommendations for initiation of ART, current and nadir CD4 T-cell counts and trajectory, HIV RNA levels, adherence issues, and patient preference.

Planned Long-Term Therapy Interruptions

Planned therapy interruptions have been contemplated in various scenarios, listed below. Research is ongoing in several of the scenarios. Therapy interruptions **cannot be recommended** at this time outside of controlled clinical trials **(AI)**.

- **In patients who initiated therapy during acute HIV infection and achieved virologic suppression**—the optimal duration of treatment and the consequences of treatment interruption are not known at this time. (See **Acute HIV Infection**.)

- **In patients who have had exposure to multiple ARV agents, have experienced ARV treatment failure, and have few treatment options available because of extensive resistance mutations**—interruption is **not recommended** unless done in a clinical trial setting **(AI)**. Several clinical trials, largely yielding negative results, but some with conflicting results, have been conducted to better understand the role of treatment interruption in these patients *[1-4]*. The largest of these studies showed negative clinical impact of treatment interruption in these patients *[1]*. The Panel notes that partial virologic suppression from combination therapy has been associated with clinical benefit *[5]*; therefore, interruption of therapy is not recommended.
- **In patients on ART who have maintained a CD4 count above the level currently recommended for treatment initiation and irrespective of whether their baseline CD4 counts were either above or below that recommended threshold**—interruption is also **not recommended** unless done in a clinical trial setting **(BI)**. (See discussion below highlighting potential adverse outcomes seen in some treatment interruption trials.)

Temporary treatment interruption to reduce inconvenience, potential long-term toxicity, and/or overall treatment cost has been considered as a strategy for patients on ART who have maintained CD4 counts above those currently recommended for initiating therapy. Several clinical trials have been designed to determine the safety of such interruptions, in which reinitiation is triggered by predetermined CD4 count thresholds. In these trials, various CD4 count levels have been set to guide both treatment interruption and reinitiation. In the SMART study, the largest of such trials with more than 5,000 subjects, interrupting treatment with CD4 counts >350 cells/mm^3 and reinitiating when <250 cells/mm^3 was associated with an increased risk of disease progression and all cause mortality compared with the trial arm of continuous ART *[6]*. In the TRIVACAN study, the same CD4 count thresholds were used for stopping and restarting treatment *[7]*. This study also showed that interruption was an inferior strategy; the interventions in both trials were stopped early because of these findings. Data from the DART trial reported a twofold increase in rates of World Health Organization (WHO) Stage 4 events/deaths in the 12-week ART cycling group among African patients achieving a CD4 count >300/mm^3 compared with the continuous ART group *[8]*. Observational data from the EuroSIDA cohort noted a twofold increase in risk of death after a treatment interruption of ≥3 months. Factors linked to increased risk of death or progression included lower CD4 counts, higher viral loads, and a prior history of AIDS *[9]*. Other studies have reported no major safety concerns *[10-12]*, but these studies had smaller sample sizes. Results have been reported from several small observational studies evaluating treatment interruption in patients doing well with nadir CD4 counts >350/mm^3, but further studies are needed to determine the safety of treatment interruption in this population *[13-14]*. There is concern that CD4 counts <500 cells/mm^3 are associated with a range of non-AIDS clinical events (e.g., cancer and heart, liver, and kidney disease) *[6, 15-16]*.

Planned long-term therapy interruption strategies **cannot be recommended** at this time outside of controlled clinical trials **(BI)** based on available data and a range of ongoing concerns.

If therapy has to be discontinued, patients should be counseled about the need for close clinical and laboratory monitoring. They should also be aware of the risks of viral rebound, acute retroviral syndrome, increased risk of HIV transmission, decline of CD4 count, HIV disease progression or death, development of minor HIV-associated manifestations such as oral thrush, development of serious non-AIDS complications, development of drug resistance, and the need for chemoprophylaxis against opportunistic infections depending on the CD4 count. Treatment interruptions often result in rapid reductions in CD4 counts.

Prior to any planned treatment interruption, a number of ARV-specific issues should be taken into consideration. These include:

- **Discontinuation of efavirenz (EFV), etravirine (ETR), or nevirapine (NVP).** The optimal interval between stopping EFV, ETR, or NVP and other ARV drugs is not known. The duration of detectable levels of EFV or NVP after discontinuation ranges from less than 1 week to more than 3 weeks *[17-18]*. Simultaneously stopping all drugs in a regimen containing these agents may result in functional monotherapy with the NNRTIs because NNRTIs have much longer half-lives than other agents. This may increase the risk of selection of NNRTI-resistant mutations. It is further complicated by evidence that certain host genetic polymorphisms may result in slower rates of clearance. Such polymorphisms may be more common among specific ethnic groups, such as African Americans and Hispanics *[18-19]*. Some experts recommend stopping the NNRTI but continuing the other ARV drugs for a period of time. The optimal time sequence for staggered component discontinuation has not been determined. A study in South Africa demonstrated that giving 4 or 7 days of zidovudine (ZDV) + lamivudine (3TC) after a single dose of NVP reduced the risk of postnatal NVP resistance from 60% to 10%–12% *[20]*. Use of nucleoside reverse transcriptase inhibitors (NRTIs) with a longer half-life such as tenofovir (TDF) plus emtricitabine (FTC) has also been shown to decrease

NVP resistance after single-dose treatment *[21]*. The findings may, however, differ in patients on chronic NVP treatment. An alternative strategy is to substitute a protease inhibitor (PI) for the NNRTI and to continue the PI with dual NRTIs for a period of time. In a post-study analysis of the patients who interrupted therapy in the SMART trial, patients who were switched from an NNRTI- to a PI-based regimen prior to interruption had a lower rate of NNRTI-resistant mutation after interruption and a greater chance of resuppression of HIV RNA after restarting therapy than those who stopped all the drugs simultaneously or stopped the NNRTI before the 2-NRTI *[22]*. The optimal duration needed to continue the PI-based regimen after stopping the NNRTI is not known. Given the potential of prolonged detectable NNRTI concentrations for more than 3 weeks, some suggest that the PI-based regimen may need to be continued for up to 4 weeks. Further research to determine the best approach to discontinuing NNRTIs is needed. Clinical data on ETR and treatment interruption is lacking but its long half-life of approximately 40 hours suggests that stopping ETR needs to be done carefully using the same suggestions for NVP and EFV for the time being.

- **Discontinuation and reintroduction of NVP**. Because NVP is an inducer of the drug-metabolizing hepatic enzymes, administration of full therapeutic doses of NVP without a 2-week, low-dose escalation phase will result in excess plasma drug levels and potentially increase the risk of toxicity. Therefore, in a patient who has interrupted treatment with NVP for more than 2 weeks, NVP should be reintroduced with a dose escalation period of 200 mg once daily for 14 days and then a 200 mg twice-daily regimen **(AII)**.
- **Discontinuation of FTC, 3TC, or TDF in patients with hepatitis B virus (HBV) coinfection**. Patients with HBV coinfection (hepatitis B surface antigen [HbsAg] or hepatitis B e antigen [HBeAg] positive) and receiving one or a combination of these NRTIs may experience an exacerbation of hepatitis upon drug discontinuation *[23-24]*. (See **Hepatitis B (HBV)/HIV Coinfection**.)

Considerations for Antiretroviral Use in Special Patient Populations

ACUTE HIV INFECTION (Updated January 10, 2011)

Panel's Recommendations:

- ***It is unknown if treatment of acute HIV infection results in long-term virologic, immunologic, or clinical benefit; treatment should be considered optional at this time (CIII).***
- ***Therapy should also be considered optional for patients with HIV seroconversion in the previous 6 months (CIII).***
- ***All pregnant women with acute or recent HIV infection should start a combination antiretroviral (ARV) regimen as soon as possible to prevent mother-to-child transmission (MTCT) of HIV (AI).***
- ***If the clinician and patient elect to treat acute HIV infection, treatment should be implemented with the goal of suppressing plasma HIV RNA to below detectable levels (AIII).***
- ***For patients with acute HIV infection in whom therapy is initiated, testing for plasma HIV RNA levels and CD4 count and toxicity monitoring should be performed as described for patients with established, chronic HIV infection (AII).***
- ***If the decision is made to initiate therapy in a person with acute HIV infection, genotypic resistance testing at baseline will be helpful in guiding the selection of an ARV regimen that can provide the optimal virologic response; this strategy is therefore recommended (AIII). If therapy is deferred, genotypic resistance testing should still be performed because the result may be useful in optimizing the virologic response when therapy is ultimately initiated (AIII).***
- ***Because clinically significant resistance to protease inhibitors (PIs) is less common than resistance to non-nucleoside reverse transcriptase inhibitors (NNRTIs) in antiretroviral therapy (ART)-naïve persons who harbor drug-resistant virus, a ritonavir (RTV)-boosted PI-based regimen should be used if therapy is initiated before drug-resistance test results are available (AIII).***

Rating of Recommendations: A = Strong; B = Moderate; C = Optional
Rating of Evidence: I = data from randomized controlled trials; II = data from well-designed nonrandomized trials or observational cohort studies with long-term clinical outcomes; III = expert opinion

An estimated 40%–90% of patients acutely infected with HIV will experience symptoms of acute retroviral syndrome characterized by fever, lymphadenopathy, pharyngitis, skin rash, myalgias/arthralgias, and other symptoms *[1-6]*. However, acute HIV infection is often not recognized by primary care clinicians because symptoms are similar to those for influenza, infectious mononucleosis, or other illnesses. Additionally, acute infection can occur asymptomatically. **Table 10** provides practitioners with guidance on the recognition, diagnosis, and management of acute HIV infection.

Diagnosis of Acute HIV Infection

Health care providers should maintain a high level of suspicion of acute HIV infection in patients who have a compatible clinical syndrome and who report recent high-risk behavior *[7]*. However, in some settings, patients may not always disclose or admit to high-risk behaviors or might not perceive their behaviors as high risk. Thus, symptoms and signs consistent with acute retroviral syndrome should motivate consideration of this diagnosis even in the absence of reported high-risk behaviors.

When acute retroviral syndrome is suspected, a plasma HIV RNA test is typically used in conjunction with an HIV antibody test to diagnose acute infection **(BII)**. Acute HIV infection is often defined by detectable HIV RNA in plasma in the setting of a negative or indeterminate HIV antibody test. A low-positive HIV RNA level (<10,000 copies/mL) may represent a false-positive test because values in acute infection are generally very high (>100,000 copies/mL) *[5-6]*. A qualitative HIV RNA test can also be used in this setting. Interest in routine screening for antibody-negative acute infection has led to select centers performing virologic testing on all antibody-negative specimens, including the use of pooled HIV RNA testing on all seronegative serum samples *[8]*. In addition, a combination HIV antigen/antibody test

(ARCHITECT), recently licensed by the Food and Drug Administration (FDA), could be used for this purpose. Patients diagnosed with acute HIV infection by a virologic test while still antibody negative or indeterminate should have confirmatory serologic testing performed over the next 3 months **(AI)**. (See **Table 10**.)

Performance of Resistance Testing

Data from the United States and Europe demonstrate that transmitted virus may be resistant to at least one ARV drug in 6%–16% of patients *[9-11]*. If the decision is made to initiate therapy in a person with acute HIV infection, genotypic resistance testing at baseline to guide the selection of an ARV regimen will likely optimize virologic response; this strategy is therefore recommended **(AIII)**. (See **Drug-Resistance Testing**.) If therapy is deferred, resistance testing should still be performed because the result may be useful in optimizing the virologic response when therapy is ultimately initiated **(AIII)**.

Treatment for Acute HIV Infection

Clinical trials information regarding treatment of acute HIV infection is limited. Ongoing trials are addressing the question of the long-term benefit of potent treatment regimens initiated during acute infection. Potential benefits and risks of treating acute infection are as follows:

- **Potential Benefits of Treating Acute Infection.** Preliminary data indicate that treatment of acute HIV infection with combination ART has a beneficial effect on laboratory markers of disease progression *[12-16]*. Theoretically, early intervention could decrease the severity of acute disease; alter the initial viral setpoint, which can affect disease progression rates; reduce the rate of viral mutation as a result of suppression of viral replication; preserve immune function; and reduce the risk of viral transmission during this highly infectious stage of disease. Additionally, although data are limited and the clinical relevance is unclear, the profound loss of gastrointestinal lymphoid tissue that occurs during the first weeks of infection may be mitigated by the early initiation of ART *[17-18]*.
- **Potential Risks of Treating Acute HIV Infection.** The potential disadvantages of initiating therapy include exposure to ART without a known clinical benefit, which could result in drug toxicities, development of drug resistance, continuous need for therapy with strict adherence, and adverse effect on quality of life.

Some of the potential benefits associated with treatment during acute infection remain uncertain and of unknown clinical relevance, while the risks are largely consistent with those for initiating therapy in chronically infected asymptomatic patients with high CD4 counts. The health care provider and the patient should be fully aware that the rationale for therapy for acute HIV infection is based on theoretical considerations, and the potential benefits should be weighed against the potential risks. For these reasons, treatment of acute HIV infection should be considered optional at this time **(CIII).** Because acute or recent HIV infection is associated with a high risk of MTCT of HIV, all HIV-infected pregnant women should start a combination ARV regimen as soon as possible to prevent perinatal transmission of HIV **(AI)** *[19]*. Following delivery, considerations regarding continuation of the ARV regimen as therapy for the mother are the same as for treatment of other nonpregnant individuals. Providers should consider enrolling patients with acute HIV infection in a clinical trial to evaluate the natural history of acute HIV and to determine the role of ART in this setting. Information regarding such trials can be obtained at **www.clinicaltrials.gov** or from local HIV treatment experts.

Treatment for Recent but Nonacute HIV Infection or Infection of Undetermined Duration

In addition to patients with acute HIV infection, some HIV clinicians also recommend consideration of therapy for patients in whom seroconversion has occurred within the previous 6 months **(CIII)**. Although the initial burst of viremia among infected adults usually resolves in 2 months, rationale for treatment during the 2- to 6-month period after infection is based on the probability that virus replication in lymphoid tissue is still not maximally contained by the immune system during this time *[20]*. In the case of pregnancy, use of a combination ARV regimen to prevent MTCT of HIV is recommended **(AI)**. For nonpregnant patients the current guidelines have provided a rationale for recommending initiation of ART in ART-naïve patients with CD4 count between 350 and 500 cells/mm^3 as well as a recommendation to consider therapy for those with CD4 count >500 cells/mm^3. (See **Initiating Antiretroviral Therapy**.) Although these recommendations are primarily based upon data from patients with chronic infection, the potential benefit of early treatment on immune recovery and on attenuation of the pathologic effects of viremia-associated inflammation and coagulation could apply to those with early HIV infection as well. Based upon all of

these considerations it is reasonable that clinicians share with patients the potential rationale for initiating ART during early HIV infection and offer treatment to those who are willing and able to commit to lifelong treatment.

Treatment Regimen for Acute or Recent HIV Infection

If the clinician and patient have made the decision to initiate ART for acute or recent HIV infection, the goal of therapy is to suppress plasma HIV RNA levels to below detectable levels **(AIII)**. Data are insufficient to draw firm conclusions regarding specific drug combinations to use in acute HIV infection. Potential combinations of agents should be those used in chronic infection. (See **What to Start**.) However, because clinically significant resistance to PIs is less common than resistance to NNRTIs in ART-naïve persons, an RTV-boosted PI-based regimen should be used if therapy is initiated before drug-resistance test results are available **(AIII)**. If resistance test results or resistance pattern of the source virus are known, this information should be used to guide the selection of the ARV regimen.

Patient Follow-up

Testing for plasma HIV RNA levels and CD4 count and toxicity monitoring should be performed as described in **Laboratory Testing for Initial Assessment and Monitoring While on Antiretroviral Therapy** (i.e., HIV RNA at initiation of therapy, after 2–8 weeks, then every 4–8 weeks until viral suppression, then every 3–4 months thereafter) **(AII)**.

Duration of Therapy for Acute or Recent HIV Infection

The optimal duration of therapy for patients with acute or recent HIV infection is unknown, but ongoing clinical trials may provide relevant data regarding these concerns. Difficulties inherent in determining the optimal duration and therapy composition for acute or recent infection (and the potential need for lifelong treatment) should be considered when counseling patients prior to initiation of therapy. Patients need to know that there are limited data regarding the benefits of stopping treatment, whereas strong data from studies in patients with chronic HIV infection show that stopping ART may be harmful *[21]*.

Table 10. Identifying, Diagnosing, and Managing Acute HIV-1 Infection (Updated January 10, 2011)

- **Suspecting acute HIV infection:** Signs or symptoms of acute HIV infection with recent (within 2–6 weeks) high risk of exposure to HIV*
  - Signs/symptoms/laboratory findings may include but are not limited to one or more of the following: fever, lymphadenopathy, skin rash, myalgia/arthralgia, headache, diarrhea, oral ulcers, leucopenia, thrombocytopenia, transaminase elevation.
  - High-risk exposures include sexual contact with a person infected with HIV or at risk of HIV, sharing of injection drug use paraphernalia, or contact of potentially infectious blood with mucous membranes or breaks in skin.*

- **Differential diagnosis:** Epstein-Barr virus (EBV)- and non-EBV (e.g., cytomegalovirus [CMV])-related infectious mononucleosis syndromes, influenza, viral hepatitis, streptococcal infection, syphilis

- **Evaluation/diagnosis of acute/primary HIV infection**
  - HIV antibody enzyme immunoassay (EIA) (rapid test if available)
    - Reactive EIA must be followed by Western blot.
    - Negative EIA or reactive EIA with negative or indeterminate Western blot should be followed by a virologic test.†
  - Positive virologic test† in this setting is consistent with acute HIV infection.
  - When acute HIV infection is diagnosed by a positive virologic test (such as HIV RNA or p24 antigen) that was preceded by a negative HIV antibody test, a confirmatory HIV antibody test should be performed over the next 3 months to confirm seroconversion.

- **Considerations for antiretroviral therapy:**
  - All pregnant women with acute or recent HIV infection should start on a combination ARV regimen as soon as possible because of the high risk of MTCT of HIV **(AI)**.
  - Treatment of acute and early HIV infection in nonpregnant persons is considered optional **(CIII)**.
  - Potentially unique benefits associated with ART during acute and early infection exist, although they remain unproven.
  - The risks of ART during acute and early infection are consistent with those for initiating ART in chronically infected asymptomatic patients with high CD4 counts.
  - If therapy is initiated, the goal should be for maintenance of maximal viral suppression.
  - Enrollment in a clinical trial should be considered.

* In some settings, behaviors conducive to acquisition of HIV infection might not be ascertained or might not be perceived as "high risk" by the health care provider or the patient or both. Thus, symptoms and signs consistent with acute retroviral syndrome should motivate consideration of this diagnosis even in the absence of reported high-risk behaviors.

† p24 antigen or HIV RNA assay. The p24 antigen is less sensitive but more specific than HIV RNA tests; HIV RNA tests are generally preferred. HIV RNA tests include quantitative branched DNA (bDNA), reverse transcriptase-polymerase chain reaction (RT-PCR), or qualitative transcription-mediated amplification (APTIMA, GenProbe).

HIV-INFECTED ADOLESCENTS AND YOUNG ADULTS (Updated January 10, 2011)

Older children and adolescents now make up the largest percentage of HIV-infected children cared for at pediatric HIV clinics in the United States. The Centers for Disease Control and Prevention (CDC) estimates that 15% of the 35,314 new HIV diagnoses reported among the 33 states that participated in confidential, name-based HIV infection reporting in 2006 were among youth 13–24 years of age *[1]*. Recent trends in HIV prevalence reveal that the disproportionate burden of HIV/AIDS among racial minorities is even greater among youth 13–19 years of age than among young adults 20–24 years of age *[2]*. Furthermore, trends for all HIV/AIDS diagnoses in 33 states from 2001 to 2006 decreased for all transmission categories except among men who have sex with men (MSM). Notably, among all black MSM, the largest increase in HIV/AIDS diagnoses occurred among youth 13–24 years of age *[3]*. HIV-infected adolescents represent a heterogeneous group in terms of sociodemographics, mode of HIV infection, sexual and substance abuse history, clinical and immunologic status, psychosocial development, and readiness to adhere to medications. Many of these factors may influence decisions concerning when to start antiretroviral therapy (ART) and what antiretroviral (ARV) medications should be used.

Most adolescents who acquire HIV are infected through high-risk behaviors. Many of them are recently infected and unaware of their HIV infection status. Thus, many are in an early stage of HIV infection, which makes them ideal candidates for early interventions, such as prevention counseling, linkage, and engagement to care. A recent study among HIV-infected adolescents and young adults presenting for care identified primary genotypic resistance mutations to ARV medications in up to 18% of the evaluable sample of recently infected youth, as determined by the detuned antibody testing assay strategy that defined recent infection as occurring within 180 days of testing *[4]*. This transmission dynamic reflects that a substantial proportion of youth's sexual partners are likely older and may be more ART experienced; thus, awareness of the importance of baseline resistance testing among recently infected youth naïve to ART is imperative.

A limited but increasing number of HIV-infected adolescents are long-term survivors of HIV infection acquired perinatally or in infancy through blood products. Such adolescents are usually heavily ART experienced and may have a unique clinical course that differs from that of adolescents infected later in life *[5]*. If these heavily ART-experienced adolescents harbor resistant virus, optimal ARV regimens should be based on the same guiding principles as for heavily ART-experienced adults. (See **Virologic and Immunogic Failure**.)

Adolescents are developmentally at a difficult crossroad. Their needs for autonomy and independence and their evolving decisional capacity intersect and compete with concrete thinking processes, risk-taking behaviors, preoccupation with self-image, and the need to "fit in" with their peers. This makes it challenging to attract and sustain adolescents' focus on maintaining their health, particularly for those with chronic illnesses. These challenges are not specific to any particular transmission mode or stage of disease. Thus, irrespective of disease duration or mode of HIV transmission, every effort must be made to engage them in care so they can improve and maintain their health for the long term.

Antiretroviral Therapy Considerations in Adolescents

Adult guidelines for ART are usually appropriate for postpubertal adolescents, because the clinical course of HIV-infected adolescents who were infected sexually or through injection drug use during adolescence is more similar to that of adults than to that of children. Adult guidelines can also be useful for postpubertal youth who were perinatally infected because these patients often have treatment challenges associated with the use of long-term ART that mirror those of ART-experienced adults, such as extensive resistance, complex regimens, and adverse drug effects.

Dosage of medications for HIV infection and opportunistic infections should be prescribed according to Tanner staging of puberty and not solely on the basis of age *[6-7]*. Adolescents in early puberty (i.e., Tanner Stages I and II) should be administered doses on pediatric schedules, whereas those in late puberty (i.e., Tanner Stage V) should follow adult dosing schedules. However, Tanner stage and age are not necessarily directly predictive of drug pharmacokinetics. Because puberty may be delayed in children who were infected with HIV perinatally *[8]*, continued use of pediatric doses in puberty-delayed adolescents can result in medication doses that are higher than the usual adult doses. Because data are not available to predict optimal medication doses for each ARV medication for this group of children, issues such as toxicity, pill or liquid volume burden, adherence, and virologic and immunologic parameters should be considered in determining when to transition from pediatric to adult doses. Youth who are in their growth spurt period (i.e., Tanner Stage III in females and Tanner Stage IV in males) and following adult or pediatric dosing guidelines and adolescents

who have transitioned from pediatric to adult doses should be closely monitored for medication efficacy and toxicity. Therapeutic drug monitoring can be considered in selected circumstances to help guide therapy decisions in this context. Pharmacokinetic studies of drugs in youth are needed to better define appropriate dosing. For a more detailed discussion, see ***Guidelines for the Use of Antiretroviral Agents in Pediatric HIV Infection*** *[9]*.

Adherence Concerns in Adolescents

HIV-infected adolescents are especially vulnerable to specific adherence problems based on their psychosocial and cognitive developmental trajectory. Comprehensive systems of care are required to serve both the medical and psychosocial needs of HIV-infected adolescents, who are frequently inexperienced with health care systems and who lack health insurance. Many HIV-infected adolescents face challenges in adhering to medical regimens for reasons that include:

- denial and fear of their HIV infection;
- misinformation;
- distrust of the medical establishment;
- fear and lack of belief in the effectiveness of medications;
- low self-esteem;
- unstructured and chaotic lifestyles;
- mood disorders and other mental illness;
- lack of familial and social support;
- absence of or inconsistent access to care or health insurance; and
- incumbent risk of inadvertent parental disclosure of the youth's HIV infection status if parental health insurance is used.

In selecting treatment regimens for adolescents, clinicians must balance the goal of prescribing a maximally potent ART regimen with realistic assessment of existing and potential support systems to facilitate adherence. Adolescents benefit from reminder systems (e.g., beepers, timers, and pill boxes) that are stylish and inconspicuous *[10]*. It is important to make medication adherence as user friendly and as little stigmatizing as possible for the older child or adolescent. The concrete thought processes of adolescents make it difficult for them to take medications when they are asymptomatic, particularly if the medications have side effects. Adherence to complex regimens is particularly challenging at a time of life when adolescents do not want to be different from their peers *[11-13]*. Directly observed therapy might be considered for selected HIV-infected adolescents such as those with mental illness *[14-18]*.

Difficult Adherence Problems

Because adolescence is characterized by rapid changes in physical maturation, cognitive processes, and life style, predicting long-term adherence in an adolescent can be very challenging. The ability of youth to adhere to therapy needs to be included as part of therapeutic decision making concerning the risks and benefits of starting treatment. Erratic adherence may result in the loss of future regimens because of the development of resistance mutations. Clinicians who care for HIV-infected adolescents frequently manage youth who, while needing therapy, pose significant concerns regarding their ability to adhere to therapy. In these cases, alternative considerations to initiation of therapy can be the following: (1) a short-term deferral of treatment until adherence is more likely or while adherence-related problems are aggressively addressed; (2) an adherence testing period in which a placebo (e.g., vitamin pill) is administered; and (3) the avoidance of any regimens with low genetic resistance barriers. Such decisions are ideally individualized to each patient and should be made carefully in context with the individual's clinical status. For a more detailed discussion on specific therapy and adherence issues for HIV-infected adolescents, see ***Guidelines for Use of Antiretroviral Agents in Pediatric HIV Infection*** *[9]*.

Special Considerations in Adolescents

Sexually transmitted infections (STIs), in particular human papilloma virus (HPV), should also be addressed in all adolescents. For a more detailed discussion on STIs, see the most recent CDC guidelines *[19]* and the pediatric opportunistic infection treatment guidelines on HPV among HIV-infected adolescents *[20]*. Family planning counseling, including a discussion of the risks of perinatal transmission of HIV and methods to reduce risks, should be provided to all youth. Providing gynecologic care for the HIV-infected female adolescent is especially important. Contraception, including the interaction of specific ARV drugs on hormonal contraceptives, and the potential for pregnancy also may alter choices of ART. As an example, efavirenz (EFV) should be used with caution in females of childbearing age and should only be prescribed after intensive counseling and education about the potential effects on the fetus, the need for close monitoring—including periodic pregnancy testing—and a commitment on the part of the teen to use effective contraception. For a more detailed discussion, see **HIV-Infected Women** and the ***Perinatal Guidelines*** *[21]*.

Transitioning Care

Given lifelong infection with HIV and the need for treatment through several stages of growth and development, HIV care programs and providers need flexibility to appropriately transition care for HIV-infected children, adolescents, and young adults. A successful transition requires an awareness of some fundamental differences between many adolescent and adult HIV care models. In most adolescent HIV clinics, care is more "teen-centered" and multidisciplinary, with primary care being highly integrated into HIV care. Teen services, such as sexual and reproductive health, substance abuse treatment, mental health, treatment education, and adherence counseling are all found in one clinic setting. In contrast, some adult HIV clinics may rely more on referral of the patient to separate subspecialty care settings, such as gynecology. Transitioning the care of an emerging young adult includes considerations of areas such as medical insurance, independence, autonomy, decisional capacity, confidentiality, and consent. Also, adult clinic settings tend to be larger and can easily intimidate younger, less motivated patients. As an additional complication to this transition, HIV-infected adolescents belong to two epidemiologically distinct subgroups: (1) those perinatally infected—who would likely have more disease burden history, complications, and chronicity; less functional autonomy; greater need for ART; and higher mortality risk; and (2) those more recently infected due to high-risk behaviors. Thus, these subgroups have unique biomedical and psychosocial considerations and needs.

To maximize the likelihood of a successful transition, facilitators to successful transitioning are best implemented early on. These include the following: (1) optimizing provider communication between adolescent and adult clinics; (2) addressing patient/family resistance caused by lack of information, stigma or disclosure concerns, and differences in practice styles; (3) preparing youth for life skills development, including counseling them on the appropriate use of a primary care provider and appointment management, the importance of prompt symptom recognition and reporting, and the importance of self-efficacy with medication management, insurance, and entitlements; (4) identifying an optimal clinic model for a given setting (i.e., simultaneous transition of mental health and/or case management versus a gradual phase-in); (5) implementing ongoing evaluation to measure the success of a selected model; (6) engaging in regular multidisciplinary case conferences between adult and adolescent care providers; (7) implementing interventions that may be associated with improved outcomes, such as support groups and mental health consultation; and (8) incorporating a family planning component into clinical care. Attention to these key areas will likely improve adherence to appointments and avert the potential for a youth to "fall through the cracks," as it is commonly referred to in adolescent medicine.

HIV AND ILLICIT DRUG USERS (IDUs) (Updated January 10, 2011)

Treatment Challenges of HIV-Infected IDUs

Injection drug use is the second-most common mode of HIV transmission in the United States. In addition, noninjection illicit drug use may facilitate sexual transmission of HIV. Injection and noninjection illicit drugs include the following: heroin, cocaine, marijuana, and club drugs (i.e., methamphetamine, ketamine, gamma-hydroxybutyrate [GHB], and amyl nitrate). The most commonly used illicit drugs associated with HIV infection are heroin and stimulants (e.g., cocaine and amphetamines); however, the use of club drugs has increased substantially in the past several years and is common among those who have HIV infection or who are at risk of HIV infection. Methamphetamine and amyl nitrate (i.e., poppers) have been the most strongly associated with high-risk sexual behavior in men who have sex with men (MSM), and the association is less consistent with the other club drugs *[1]*.

All illicit drugs have been associated with depression and anxiety, either as part of the withdrawal process or as a consequence of repeated use. This is particularly relevant in the treatment of HIV infection because depression is one of the strongest predictors of poor adherence and poor treatment outcomes *[2]*. Although treatment of HIV disease in this population can be successful, IDUs who have HIV disease present special treatment challenges. These may include the following: (1) an array of complicating comorbid medical and mental health conditions; (2) limited access to HIV care; (3) inadequate adherence to therapy; (4) medication side effects and toxicities; (5) the need for substance abuse treatment; and (6) drug interactions that can complicate HIV treatment *[3]*.

Underlying health problems among injection and noninjection drug users result in increased morbidity and mortality, either independent of or accentuated by HIV disease. Many of these problems are the consequence of prior exposures to infectious pathogens from nonsterile needle and syringe use. Such problems can include hepatitis B or C virus infection, tuberculosis, skin and soft tissue infections, recurrent bacterial pneumonia, and endocarditis. Other morbidities such as alteration in levels of consciousness and neurologic and renal disease are not uncommon. Furthermore, these comorbidities are associated with a higher risk of drug overdoses in IDUs with HIV disease, due in part to respiratory, hepatic, and neurological impairments *[4]*. Successful HIV therapy for IDUs often rests upon acquiring familiarity with and providing care for these comorbid conditions and overdose prevention support.

IDUs have less access to HIV care and are less likely to receive antiretroviral therapy (ART) than other populations *[5-6]*. Factors associated with low rates of ART among IDUs include active drug use, younger age, female gender, suboptimal health care, recent incarceration, lack of access to rehabilitation programs, and lack of expertise among health care providers *[5-6]*. The typically unstable, chaotic life patterns of many IDUs; the powerful pull of addictive substances; and common misperceptions about the dangers, impact, and benefits of ART all contribute to decreased adherence *[7]*. The chronic and relapsing nature of substance abuse as a biologic and medical disease, compounded by the high rate of mental illness that antedates and/or is exacerbated by illicit substance use, additionally complicate the relationship between health care workers and IDUs *[8-9]*. The first step in provision of care and treatment for these individuals is to recognize the existence of a substance abuse problem. Whereas this is often open and obvious, patients may hide such behaviors from clinicians. Assessment of a patient for substance abuse should be part of routine medical history taking and should be done in a clinical, straightforward, and nonjudgmental manner.

Treatment Efficacy in HIV-Infected Illicit Drug Use Populations

Although IDUs are underrepresented in HIV therapy clinical trials, available data indicate that—when they are not actively using drugs— efficacy of ART in IDUs is similar to that seen in other populations *[10]*. Furthermore, therapeutic failure in this population generally correlates with the degree that drug use disrupts daily activities rather than with drug use *per se [11]*. Providers need to remain attentive to the possible impact these factors have upon the patient before and during prescription of ART. Although many IDUs can sufficiently control their drug use over long enough periods of time to benefit from care**,** substance abuse treatment is often necessary for successful HIV management.

Close collaboration with substance abuse treatment programs and proper support and attention to this population's special multidisciplinary needs are critical components of successful HIV treatment. Essential to this end are accommodating and flexible, community-based HIV care sites that are characterized by familiarity with and

nonjudgmental expertise in management of drug users' wide array of needs and in development of effective strategies to promote medication adherence *[9]*, including, if available, the use of adherence support mechanisms such as modified directly observed therapy, which has shown promise in this population *[12]*.

Antiretroviral Agents and Opioid Substitution Therapy

IDUs are more likely to experience an increased frequency of side effects and toxicities of ART. Although not systematically studied, this is likely because underlying hepatic, renal, neurologic, psychiatric, gastrointestinal, and hematologic disorders are highly prevalent among IDUs. Selection of ARV agents in this population should be made with consideration of these comorbid conditions. Opioid substitution therapies such as methadone and buprenorphine/naloxone and extended release naltrexone are commonly used for management of opioid dependence in HIV infected-patients.

Methadone and ART. Methadone, an orally administered, long-acting opioid agonist, is the most common pharmacologic treatment for opioid addiction. Its use is associated with decreased heroin use, decreased needle sharing, and improved quality of life. Because of its opioid-induced effects on gastric emptying and the metabolism of cytochrome P (CYP) 450 isoenzymes 2B6, 3A4, and 2D6, pharmacologic effects and interactions with ARV agents may commonly occur *[13]*. These may diminish the effectiveness of either or both therapies by causing opioid withdrawal or overdose, increased methadone toxicity, and/or decreased ARV efficacy. Efavirenz (EFV), nevirapine (NVP), and lopinavir/ritonavir (LPV/r) have been associated with significant decreases in methadone levels. It is necessary to inform patients and substance abuse treatment facilities of the likelihood of this interaction. The clinical effect is usually seen after 7 days of coadministration and may be managed by increasing the methadone dosage, usually in 5-mg to10-mg increments daily until the desired effect is achieved.

Buprenorphine and ART. Buprenorphine, a partial μ-opioid agonist, is administrated sublingually and is often coformulated with naloxone. It is being increasingly used for opioid dependence treatment. The lower risk of respiratory depression and overdose compared with methadone allows it to be prescribed by physicians in primary care for the treatment of opioid dependency. This flexible treatment setting could be of significant value to opioid-addicted HIV-infected patients who require ART because it enables one physician or program to provide both medical and substance abuse services. Limited information is currently available about interactions between buprenorphine and antiretroviral agents *[13-14]*. Findings from available studies show a more favorable drug interaction profile than that of methadone.

Naltrexone and ART. A once monthly extended-release intramuscular formulation of naltrexone was recently approved for prevention of relapse in patients who have undergone an opioid detoxification program. Naltrexone is also indicated for treatment of alcohol dependency. Naltrexone is not metabolized via the CYP 450 enzyme system and is not expected to interact with protease inhibitors (PIs) or nonnucleoside reverse transcriptase inhibitors (NNRTIs) *[15]*.

Table 11 provides the currently available pharmacokinetic interaction data that clinicians can use as a guide for managing patients receiving ART and methadone or buprenorphine. Particular attention is needed concerning communication between HIV care providers and drug treatment programs regarding additive drug toxicities and drug interactions resulting in opiate withdrawal or excess.

Methylenedioxymethamphetamine (MDMA), GHB, ketamine, and methamphetamine all have the potential to interact with ARV agents because all are metabolized, at least in part, by the CYP 450 system. Overdoses secondary to interactions between the party drugs (i.e., MDMA or GHB) and PI-based ART have been reported *[16]*.

Summary

It is usually possible over time to support most active drug users such that acceptable adherence levels with ARV agents can be achieved *[17-18]*. Providers must work to combine all available resources to stabilize an active drug user in preparation for ART. This should include identification of concurrent medical and psychiatric illnesses, drug treatment, needle and syringe exchange, reduction in high-risk sexual behavior, and harm reduction strategies. A

history of drug use alone is insufficient reason to withhold ART because individuals with a history of prior drug use have adherence rates similar to individuals who do not abuse drugs.

Important considerations in the selection of successful regimens and the provision of appropriate patient monitoring in this population include supportive clinical sites; linkage to substance abuse treatment; and awareness of the interactions between illicit drugs and ARV agents, including the increased risk of side effects and toxicities. Simple regimens should be considered to enhance medication adherence. Preference should be given to ARV agents that have a lower risk of hepatic and neuropsychiatric side effects, simple dosing schedules, and minimal interaction with methadone.

Table 11. Drug Interactions between Antiretroviral Agents and Drugs Used to Treat Opioid Addiction (January 10, 2011)

Concomitant Drug	Antiretroviral Class/Drug	Pharmacokinetic Interactions Recommendations/Clinical Comments
Buprenorphine	EFV	buprenorphine AUC ↓ 50%; norbuprenorphine* AUC ↓ 71% No withdrawal symptoms reported. No dosage adjustment recommended; however, monitor for withdrawal symptoms.
	ATV	buprenorphine AUC ↑ 93%; norbuprenorphine AUC ↑ 76%; ↓ ATV levels possible Do not coadminister buprenorphine with unboosted ATV.
	ATV/r	buprenorphine AUC ↑ 66%; norbuprenorphine AUC ↑ 105% Monitor for sedation. Buprenorphine dose reduction may be necessary.
	DRV/r	buprenorphine: no significant effect, norbuprenorphine AUC ↑ 46% and C_{min} ↑ 71% No dose adjustment necessary.
	TPV/r	buprenorphine: no significant effect; norbuprenorphine AUC, C_{max}, and C_{min} ↓ 80%; TPV Cmin ↓ 19%–40% Consider monitoring TPV level.
	3TC, ddI, TDF, ZDV, NVP, LPV/r, NFV	No significant effect No dosage adjustment necessary.
	ABC, d4T, FTC, ETR, FPV +/- RTV, IDV +/- RTV, SQV/r, RAL, MVC, T20	No data

Table 11. Drug Interactions between Antiretroviral Agents and Drugs Used to Treat Opioid Addiction

Concomitant Drug	Antiretroviral Class/Drug	Pharmacokinetic Interactions Recommendations/Clinical Comments
Methadone	ABC	methadone clearance ↑ 22% No dosage adjustment necessary.
	d4T	d4T AUC ↓ 23% and C_{max} ↓ 44% No dosage adjustment necessary.
	ZDV	ZDV AUC ↑ 29%–43% Monitor for ZDV-related adverse effects.
	EFV	methadone AUC ↓ 52% Opioid withdrawal common; increased methadone dose often necessary.
	NVP	methadone AUC ↓ 41% NVP: no significant effect Opioid withdrawal common; increased methadone dose often necessary.
	ATV/r, DRV/r, FPV/r, IDV/r, LPV/r, SQV/r, TPV/r	With ATV/r, DRV/r, FPV/r: R-methadone† AUC ↓ 16%–18%; With LPV/r: methadone AUC ↓ 26%–53%; With SQV/r 1,000/100mg BID: R-methadone AUC ↓ 19%; With TPV/r: R-methadone AUC ↓ 48% Opioid withdrawal unlikely but may occur. No adjustment in methadone usually required; however, monitor for opioid withdrawal and increase methadone dose as clinically indicated.
	FPV	No data with FPV (unboosted) With APV: R-methadone C_{min} ↓ 21%, AUC no significant change Monitor and titrate methadone as clinically indicated. The interaction with FPV is presumed to be similar.
	NFV	methadone AUC ↓ 40% Opioid withdrawal rarely occurs. Monitor and titrate dose as clinically indicated. May require increased methadone dose.
	ddI (EC capsule), 3TC, TDF, ETR, RTV, ATV, IDV, RAL	No significant effect No dosage adjustment necessary.
	FTC, MVC, T20	No data

*Norbuprenorphine is an active metabolite of buprenorphine.
† R-methadone is the active form of methadone.

Acronyms: 3TC = lamivudine, d4T = stavudine, T20 = enfuvirtide, ABC = abacavir, APV = amprenavir, ATV = atazanavir, ATV/r = atazanavir/ritonavair, ddI = didanosine, DRV/r = darunavir/ritonavir, EFV = efavirenz, ETR = etravirine, FPV = fosamprenavir, FPV/r = fosamprenavir/ritonavir, FTC = emtricitabine, IDV = indinavir, IDV/r = indinavir/ritonavir, LPV/r = lopinavir/ritonavir, MVC = maraviroc, NFV = nelfinavir, NVP = nevirapine, RAL = raltegravir, RTV = ritonavir, SQV/r = sacquinavir/ritonavir, TDF = tenofovir, TPV = tipranavir, TPV/r = tipranavir/ritonavir, ZDV = zidovudine

HIV-INFECTED WOMEN (Updated January 10, 2011)

Panel's Recommendations:

- ***The indications for initiation of antiretroviral therapy (ART) and the goals of treatment are the same for HIV-infected women as for other HIV-infected adults and adolescents (AI).***
- ***Women taking antiretroviral (ARV) drugs that have significant pharmacokinetic interactions with oral contraceptives should use an additional or alternative contraceptive method for prevention of unintended pregnancy (AIII).***
- ***In pregnant women, an additional goal of therapy is prevention of mother-to-child transmission (PMTCT), with a goal of maximal viral suppression to reduce the risk of transmission of HIV to the fetus and newborn (AI).***
- ***Genotypic resistance testing is recommended for all HIV-infected persons, including pregnant women, prior to initiation of ART (AIII) and for women entering pregnancy with detectable HIV RNA levels while on therapy (AI).***
- ***When selecting an ARV combination regimen for a pregnant woman, clinicians should consider the known safety, efficacy, and pharmacokinetic data of each agent during pregnancy (AIII).***
- ***Efavirenz (EFV) should be avoided in a pregnant woman during the first trimester or in a woman who desires to become pregnant or who does not or cannot use effective and consistent contraception (AIII).***
- ***Clinicians should consult the most current Health and Human Services (HHS) Perinatal Guidelines when designing a regimen for a pregnant woman (AIII).***

Rating of Recommendations: A = Strong; B = Moderate; C = Optional
Rating of Evidence: I = data from randomized controlled trials; II = data from well-designed nonrandomized trials or observational cohort studies with long-term clinical outcomes; III = expert opinion

This section provides discussion of some basic principles and unique considerations to follow when caring for HIV-infected women in general and for pregnant HIV-infected women. Clinicians who provide care for pregnant women should consult the current ***Perinatal Guidelines*** *[1]* for in-depth discussion and management assistance.

Gender Considerations in Antiretroviral Therapy

In general, studies to date have not shown differences in virologic efficacy of ART by gender *[2-4]*, although a number of studies have suggested that gender or sex may influence the frequency, presentation, and severity of selected ARV-related adverse events *[5]*. Although data are limited, there is also evidence that women may metabolize and respond to specific medications, including ARV drugs, differently than men *[6-8]*.

Adverse Effects:

- ***Nevirapine (NVP)-associated hepatotoxicity***: NVP has been associated with an increased risk of symptomatic, potentially fatal, and often rash-associated liver toxicity among ARV-naïve individuals; women with higher CD4 counts (>250 cells/mm^3) appear to be at greatest risk *[9-12]*. It is generally recommended that NVP not be prescribed to ARV-naïve women who have CD4 counts >250 cells/mm^3 unless there is no other alternative and the benefit from NVP outweighs the risk of hepatotoxicity **(AI)**.
- ***Lactic acidosis***: There appears to be a female predominance in the increased incidence of symptomatic and even fatal lactic acidosis associated with prolonged exposure to nucleoside reverse transcriptase inhibitors (NRTIs). Lactic acidosis is most common with stavudine (d4T), didanosine (ddI), and zidovudine (ZDV); however, it can occur with other NRTIs *[13]*.
- ***Metabolic complications***: A few studies have compared women to men in terms of metabolic complications associated with ARV use. HIV-infected women are more likely to experience increases in central fat with ART and are less likely to have triglyceride elevations on treatment *[14-15]*. Women have an increased risk of osteopenia/osteoporosis, particularly after menopause, and this risk may be exacerbated by HIV and ART *[16-17]*. At the present time, none of these differences requires a change in recommendations regarding treatment or monitoring.

Women of Childbearing Potential

All women of childbearing potential should be offered preconception counseling and care as a component of routine primary medical care. Discussion should include special considerations with ARV use when trying to conceive and during pregnancy. (See ***Perinatal Guidelines*** *[1]*). The most vulnerable period in fetal organogenesis is early in gestation, often before pregnancy is recognized. Sexual activity, reproductive plans, and use of effective contraception to prevent unintended pregnancy should be discussed with women. As part of the evaluation for initiating ART, women should be counseled about the potential teratogenic risk of EFV-containing regimens, should pregnancy occur. EFV-containing regimens should be avoided in women who are trying to conceive or who are sexually active and not using effective and consistent contraception.

Effective contraception should be available for women who wish to prevent pregnancy. Several protease inhibitors (PIs) and non-nucleoside reverse transcriptase inhibitors (NNRTIs) have drug interactions with combined oral contraceptives (COCs). Interactions include either a decrease or an increase in blood levels of ethinyl estradiol, norethindrone, or norgestimate (see **Tables 15a and b**), which potentially decrease contraceptive efficacy or increase estrogen- or progestin-related adverse effects (e.g., thromboembolic risk). In general, women who are on any of these ARV drugs should use an alternative or additional method of contraception **(AIII)**. Although there is minimal information about drug interactions with use of newer combined hormonal contraceptive methods (e.g., transdermal patch, vaginal ring), an additional or alternative contraceptive method should also be considered on the basis of established drug interactions between ARVs and COCs. Data on drug interactions between ARVs and progestin-only contraceptive methods are limited; however, recent data have found no significant changes in ARV drug concentrations of nelfinavir (NFV), NVP, or EFV when used with depot medroxyprogesterone acetate (DMPA), and there is no evidence of reduced DMPA effectiveness *[18-20]*. Intrauterine devices have been shown to be safe and effective in HIV-infected women *[21-22]*. Counseling about reproductive issues should be provided on an ongoing basis.

Pregnant Women

The use of combination ARV regimens is recommended for all HIV-infected pregnant women, regardless of virologic, immunologic, or clinical parameters, primarily for prevention of HIV transmission from mother to child and for treatment of maternal infection **(AI)**. Pregnant HIV-infected women should be counseled regarding the known benefits versus potential risks of ARV use during pregnancy to the mother, fetus, and newborn. A woman's decision regarding ARV use should be respected. Coercive and punitive policies undermine provider-patient trust and could discourage women from seeking prenatal care and adopting health care behaviors that optimize maternal, fetal, and neonatal well-being.

Prevention of Mother-to-Child Transmission (PMTCT). Both reduction of HIV RNA levels and use of ARVs appear to have an independent effect on reduction of perinatal transmission of HIV *[23-25]*. The goal of ARV use is to achieve maximal and sustained suppression of HIV RNA levels during pregnancy, but most critically by late pregnancy and the time of delivery, when most transmission occurs.

Genotypic resistance testing is recommended for all pregnant women prior to ARV initiation **(AIII)** and for women entering pregnancy with detectable HIV RNA levels while on therapy **(AI)**. Optimal prevention of perinatal transmission may require initiation of ARV before results of resistance testing are available. If results demonstrate the presence of significant mutation(s) that may confer resistance to the prescribed ARV regimen, the regimen should be modified.

Long-term follow-up is recommended for all infants born to women who have received ARVs during pregnancy, regardless of the infant's HIV status.

Regimen Considerations. Pregnancy should not preclude the use of optimal drug regimens. However, recommendations regarding the choice of ARVs for treatment of HIV-infected pregnant women are subject to unique considerations, which may result in different specific recommendations regarding timing of initiation and choice of drugs. These considerations include the following:

- potential changes in pharmacokinetics, and thus dosing requirements, which result from physiologic changes associated with pregnancy,
- potential ARV-associated adverse effects in pregnant women,
- effect on the risk of perinatal transmission of HIV, and
- potential short- and long-term effects of the ARV on the fetus and newborn, which are unknown for many drugs.

Clinicians should review the ***Perinatal Guidelines*** *[1]* for a detailed discussion of drug choices. Combination drug regimens are considered the standard of care in pregnancy, both for the treatment of HIV infection and for PMTCT. ZDV by intravenous infusion to the mother during labor and orally to the neonate for 6 weeks is recommended irrespective of antenatal regimen chosen.

There are some specific differences in treatment recommendations in pregnancy based on the above considerations.

NRTIs:

- Although no longer considered a preferred NRTI for non-pregnant adults and adolescents, ZDV is still one of the preferred NRTI drugs when used in pregnancy based on long-term effectiveness in prevention of transmission and safety data in pregnancy (for more detailed discussion, see the ***Perinatal Guidelines*** *[1]*). However, ZDV should not be included in a regimen if there is severe toxicity, documented resistance, or if the woman is also receiving d4T. Women already on a fully suppressive regimen that does not include ZDV should continue on the regimen **(AIII)**.
- The syndrome of lactic acidosis and hepatic steatosis may present with similar signs and symptoms to certain pregnancy-specific disorders (i.e., acute fatty liver of pregnancy, HELLP [hemolysis, elevated liver enzymes, low platelet count] syndrome). Given this similarity, clinicians should have a low threshold for considering lactic acidosis in the differential diagnosis and for appropriate evaluation of pregnant HIV-infected women receiving NRTIs with a consistent clinical picture, particularly if they have accompanying hepatitis or pancreatitis.

NNRTIs:

- EFV-containing regimens **should be avoided** in the first trimester, because significant teratogenic effects were seen in primate studies at drug exposures similar to those achieved during human exposure **(AIII)**. In addition, several cases of neural tube defects have now been reported after early human gestational exposure to EFV *[26-27]*. EFV may be considered for use after the first trimester if indicated because of toxicity, resistance, drug interaction issues, or other clinical concerns (e.g., adherence, presentation after first trimester on EFV-containing regimen) *[28]*.
- Although there is no evidence that pregnancy additionally increases risk of NVP toxicity over that in nonpregnant women *[29]*, NVP should not be initiated as a component of a combination regimen in ARV-naïve pregnant women who have CD4 counts >250 cells/mm^3 unless the benefit clearly outweighs the risk **(AII)**.

PIs:

- Several small studies show that optimal levels of several PIs may not be achieved in pregnancy with standard dosing, especially in the third trimester, although the clinical relevance of this is unknown *[30-32]*. For more information regarding potential dosing alterations, please refer to the ***Perinatal Guidelines*** *[1]*. Once-daily lopinavir/ritonavir (LPV/r) dosing is not recommended in pregnancy, because there are no data to address adequacy of blood levels with this dosing regimen **(BII)**.

Minimal data exist on the use of newer agents, including entry inhibitors and integrase inhibitors, in pregnancy.

Clinicians who are treating HIV-infected pregnant women are strongly encouraged to report cases of prenatal exposure to ARVs (either administered alone or in combinations) to the Antiretroviral Pregnancy Registry (**http://www.apregistry.com**). The registry collects observational data regarding exposure to FDA-approved ARV drugs during pregnancy for the purpose of assessing potential teratogenicity. For more information regarding selection and use of ART during pregnancy, refer to the ***Perinatal Guidelines*** *[1]*. Lastly, women should be counseled regarding the avoidance of breastfeeding. Continued clinical, immunologic, and virologic follow-up should be done as recommended for non-pregnant adults and adolescents.

Discontinuation of Antiretroviral Therapy Postpartum

Following delivery, considerations regarding continuation of ART for maternal therapeutic indications are the same as for other non-pregnant individuals. The decision of whether to continue therapy after delivery should take into account current recommendations for initiation of ART, current and nadir CD4 T-cell counts and trajectory, HIV RNA levels, adherence issues, and patient preference. A study from the Women and Infants Transmission Study (WITS) of women who were ARV naïve prior to pregnancy and had CD4 counts >350/mm^3 *[33]* found no significant differences in CD4 count, viral load, or disease progression among those who did or did not continue ART after delivery through 12 months postpartum. In most cases, when drugs are discontinued postnatally, all drugs should be stopped simultaneously. However, if therapy includes an NNRTI, stopping all regimen components simultaneously may result in functional monotherapy because of the long half-life of the NNRTI, which may increase risk of resistance. In one study, NVP resistance was identified in 16% of women on an NVP-containing regimen despite continuation of the NRTI backbone for 5 days after stopping NVP *[34]*. For women whose antepartum regimen included an NNRTI and who plan to stop ARV prophylaxis after delivery, consideration should be given to stopping the NNRTI and continuing the other ARV or switching from an NNRTI to a PI prior to interruption and continuing the PI with the other ARV for a period of time before electively stopping ART. The optimal interval between stopping an NNRTI and the other ARV is not known; at least 7 days is recommended but some experts recommend continuing the other ARV or substituting a PI plus two other agents for up to 30 days. Additional research is needed to assess appropriate strategies for stopping NNRTI-containing combination regimens after delivery in situations when ongoing maternal treatment is not indicated and to assess the effect of limited-duration, fully suppressive ARV prophylaxis in pregnancy on future treatment efficacy. (See **Discontinuation or Interruption of Antiretroviral Therapy**.)

In HIV and hepatitis B virus (HBV) co-infected pregnant women who are receiving ART only for perinatal prophylaxis and who are stopping therapy after delivery, careful clinical and laboratory monitoring for HBV flare should be performed postpartum when ARVs active against HBV are discontinued. However, if treatment for HBV is indicated, a full combination regimen for both HIV and HBV infection should be continued. (See **Initiating Antiretroviral Therapy**.)

HIV-2 INFECTION (Updated January 10, 2011)

HIV-2 infection is endemic in West Africa. Although HIV-2 has had only limited spread outside this area, it should be considered in persons of West African origin or those who have had sexual contact or shared needles with persons of West African origin. The prevalence of HIV-2 infection is also disproportionately high in countries with strong socioeconomic ties to West Africa (e.g., France; Spain; Portugal; and former Portuguese colonies such as Brazil, Angola, Mozambique, and parts of India near Goa).

The clinical course of HIV-2 infection is generally characterized by a longer asymptomatic stage, lower plasma HIV-2 viral loads, and lower mortality rates compared with HIV-1 infection *[1-2]*. However, HIV-2 infection can progress to AIDS, and thus antiretroviral therapy (ART) may become necessary during the course of infection. Concomitant HIV-1 and HIV-2 infection may occur and should be considered in patients from an area with high prevalence of HIV-2. In the appropriate epidemiologic setting, HIV-2 infection should be suspected in patients with clinical conditions suggestive of HIV infection but with atypical serologic results (e.g., a positive screening assay with an indeterminate HIV-1 Western blot) *[3]*. The possibility of HIV-2 infection should also be considered in the appropriate epidemiologic setting in patients with serologically confirmed HIV infection but low or undetectable viral loads or in those with declining CD4 counts despite apparent virologic suppression on ART.

The Multispot HIV-1/HIV-2 Rapid Test (Bio-Rad Laboratories) is Food and Drug Administration (FDA) approved for differentiating HIV-1 from HIV-2 infection. Commercially available HIV-1 viral load assays do not reliably detect or quantify HIV-2, and no HIV-2 commercial viral load assays are currently available *[4-5]*. Most studies reporting HIV-2 viral loads use "in-house" assays that are not widely available, making it difficult to monitor virologic response in the clinical setting. In addition, no validated HIV-2 genotypic or phenotypic antiretroviral (ARV) resistance assays are available.

To date, there have been no randomized trials addressing the question of when to start ART or the choice of initial or second-line therapy for HIV-2 infection *[6]*; thus, the optimal treatment strategy has not been defined. HIV-2 appears intrinsically resistant to non-nucleoside reverse transcriptase inhibitors (NNRTIs) *[7]* and to enfuvirtide *[8]*. *In vitro* data suggest HIV-2 is sensitive to the currently available nucleoside reverse transcriptase inhibitors (NRTIs), although with a lower barrier to resistance than HIV-1 *[9-10]*. Variable sensitivity among protease inhibitors (PIs) has been reported; lopinavir (LPV), saquinavir (SQV), and darunavir (DRV) are more active against HIV-2 than other approved PIs *[11-14]*. The integrase inhibitor, raltegravir (RAL) *[15]*, and the CCR5 antagonist, maraviroc (MVC), appear active against some HIV-2 isolates, although no approved assays to determine HIV-2 coreceptor tropism exist and HIV-2 is known to utilize multiple minor coreceptors in addition to CCR5 and CXCR4 *[16]*. Several small studies suggest poor responses among HIV-2 infected individuals treated with some ARV regimens, including dual-NRTI regimens, regimens containing two NRTIs + NNRTI, and some unboosted PI-based regimens including nelfinavir (NFV) or indinavir (IDV) plus zidovudine (ZDV) and lamivudine(3TC) *[6, 17-19]*. Clinical data on the utility of triple-NRTI regimens are conflicting *[20-21]*. In general, boosted PI-containing regimens have resulted in more favorable virologic and immunologic responses *[21]*. One small study suggested satisfactory responses to lopinavir/ritonavir (LPV/r)-containing regimens in 17 of 29 (59%) of ARV-naïve subjects *[22]*.

Resistance-associated mutations develop commonly in HIV-2 patients on therapy *[17, 21, 23]*. Genotypic algorithms used to predict drug resistance in HIV-1 may not be applicable to HIV-2, because pathways and mutational patterns leading to resistance may differ *[10, 21, 24]*. CD4 cell recovery on therapy may be poor *[25]*, suggesting that more reliable methods for monitoring disease progression and treatment efficacy in HIV-2 infection are needed.

Some groups have recommended specific preferred and alternative regimens for initial therapy of HIV-2 infection *[24]*, though as yet there are no controlled trial data to reliably predict their success. Until more definitive data are available in an ART-naïve patient with HIV-2 mono-infection or with HIV-1/HIV-2 dual infection who requires treatment, clinicians should initiate a regimen containing two NRTIs and a boosted PI. Monitoring of virologic response in such patients is problematic because of the lack of a commercially available HIV-2 viral load assay; however, clinical and CD4 count improvement can be used to assess treatment response.

Considerations for Antiretroviral Use in Patients with Coinfections

HEPATITIS B (HBV)/HIV COINFECTION (January 10, 2011)

Panel's Recommendations:

- ***Prior to intiation of antiretroviral therapy (ART), all patients who test positive for hepatitis B surface antigen (HBsAg) should be tested for hepatitis B virus (HBV) DNA using a quantitative assay to determine the level of HBV replication (AIII).***
- ***Because emtricitabine (FTC), lamivudine (3TC), and tenofovir (TDF) have activity against both HIV and HBV, if HBV or HIV treatment is needed, ART should be initiated with the combination of TDF + FTC or TDF + 3TC as the nucleoside reverse transcriptase inhibitor (NRTI) backbone of a fully suppressive antiretroviral (ARV) regimen (AI).***
- ***If HBV treatment is needed and TDF cannot safely be used, the alternative recommended HBV therapy is entecavir in addition to a fully suppressive ARV regimen (BI). Other HBV treatment regimens include peginterferon alfa monotherapy or adefovir in combination with 3TC or FTC or telbivudine in addition to a fully suppressive ARV regimen (BII).***
- ***Entecavir has activity against HIV; its use for HBV treatment without ART in patients with dual infection may result in the selection of the M184V mutation that confers HIV resistance to 3TC and FTC. Therefore, entecavir must be used in addition to a fully suppressive ARV regimen when used in HIV/HBV-coinfected patients (AII).***
- ***Discontinuation of agents with anti-HBV activity may cause serious hepatocellular damage resulting from reactivation of HBV; patients should be advised against self-discontinuation and carefully monitored during interruptions in HBV treatment (AII).***
- ***If ART needs to be modified due to HIV virologic failure and the patient has adequate HBV suppression, the ARV drugs active against HBV should be continued for HBV treatment in combination with other suitable ARV agents to achieve HIV suppression (AIII).***

Rating of Recommendations: A = Strong; B = Moderate; C = Optional
Rating of Evidence: I = data from randomized controlled trials; II = data from well-designed nonrandomized trials or observational cohort studies with long-term clinical outcomes; III = expert opinion

Approximately 5%–10% of HIV-infected persons also have chronic HBV infection, defined as testing positive for HBsAg for more than 6 months *[1]*. The progression of chronic HBV to cirrhosis, end-stage liver disease, and/or hepatocellular carcinoma is more rapid in HIV-infected persons than in persons with chronic HBV alone *[2]*. Conversely, chronic HBV does not substantially alter the progression of HIV infection and does not influence HIV suppression or CD4 cell responses following ART initiation *[3-4]*. However, several liver-associated complications that are ascribed to flares in HBV activity, discontinuation of dually active ARVs, or toxicity of ARVs can affect the treatment of HIV in patients with HBV coinfection *[5-7]*. These include the following:

- FTC, 3TC, and TDF are approved ARVs that also have antiviral activity against HBV. Discontinuation of these drugs may potentially cause serious hepatocellular damage resulting from reactivation of HBV *[8]*.
- Entecavir has activity against HIV; its use for HBV treatment without ART in patients with dual infection may result in the selection of the M184V mutation that confers HIV resistance to 3TC and FTC. Therefore, entecavir must be used in addition to a fully suppressive ARV regimen when used in HIV/HBV-coinfected patients **(AII)** *[9]*.
- 3TC-resistant HBV is observed in approximately 40% of patients after 2 years on 3TC for chronic HBV and in approximately 90% of patients after 4 years when 3TC is used as the only active drug for HBV in coinfected patients. Therefore, 3TC or FTC should be used in combination with other anti-HBV drugs **(AII)** *[10]*.
- Immune reconstitution after initiation of treatment for HIV and/or HBV can be associated with elevation in transaminases, possibly because HBV is primarily an immune-mediated disease *[11]*.
- Some ARV agents can cause increases in transaminase levels. The rate and magnitude of these increases are higher with HBV coinfection *[12-13]*. The etiology and consequences of these changes in liver function tests are unclear

because continuation of ART may be accompanied by resolution of the changes. Nevertheless, some experts suspend the implicated agent(s) when the serum alanine transferase (ALT) level is increased to 5–10 times the upper limit of normal. However, in HIV/HBV-coinfected persons, increases in transaminase levels can herald hepatitis B e antigen (HBeAg) seroconversion due to immune reconstitution, so the cause of the elevations should be investigated prior to the decision to discontinue medications. In persons with transaminase increases, HBeAg seroconversion should be evaluated by testing for HBeAg and anti-HBe as well as HBV DNA levels.

Recommendations for HBV/HIV-Coinfected Patients

- All patients with chronic HBV should be advised to abstain from alcohol, assessed for immunity to hepatitis A virus (HAV) infection (anti-HAV antibody total) and vaccinated if nonimmune, advised on methods to prevent HBV transmission (methods that do not differ from those to prevent HIV transmission), and evaluated for the severity of HBV infection as outlined in the ***Guidelines for Prevention and Treatment of Opportunistic Infections in HIV-Infected Adults and Adolescents*** *[14]*.

- Prior to intiation of ART, all persons who test positive for HBsAg should be tested for HBV DNA using a quantitative assay to determine the level of HBV replication **(AIII)**. Persons with chronic HBV infection already receiving ART active against HBV should undergo quantitative HBV DNA testing every 6–12 months to determine the effectiveness of therapy in suppressing HBV replication. The goal of HBV therapy with NRTIs is to prevent liver disease complications by sustained suppression of HBV replication to the lowest achievable level.

- **If not yet on therapy and HBV or HIV treatment is needed:** In persons without HIV infection, the recommended anti-HBV drugs for the treatment of persons naïve to HBV therapy are TDF and entecavir *[15-16]*. In HIV-infected patients, however, only TDF can be considered part of the ARV regimen; entecavir has weak anti-HIV activity and must not be considered part of an ARV regimen. In addition, only TDF is fully active for the treatment of persons with known or suspected 3TC-resistant HBV infection. To avoid selection of HBV-resistant variants, when possible, these agents should not be used as the only agent with anti-HBV activity in an ARV regimen **(AIII)**.

  Preferred regimen. The combination of TDF + FTC or TDF + 3TC should be used as the NRTI backbone of a fully suppressive ARV regimen and for the treatment of HBV infection *[17-19]* **(AII)**.

  Alternative regimens. If TDF cannot safely be used**,** entecavir should be used in addition to a fully suppressive ARV regimen **(AII)**; importantly, entecavir should not be considered to be a part of the ARV regimen *[20]* **(BII)**. Due to a partially overlapping HBV-resistance pathway, it is not known if the combination of entectavir + 3TC or FTC will provide additional virologic or clinical benefit compared with entecavir alone. In persons with known or suspected 3TC-resistant HBV infection, the entecavir dose should be increased from 0.5 mg/day to 1 mg/day. However, entecavir resistance may emerge rapidly in patients with 3TC-resistant HBV infection. Therefore, entecavir should be used with caution in such patients with frequent monitoring (~ every 3 months) of the HBV DNA level to detect viral breakthrough. Other HBV treatment regimens include peginterferon alfa monotherapy or adefovir in combination with 3TC or FTC or telbivudine in addition to a fully suppressive ARV regimen *[17, 21-22]*; however, data on these regimens in persons with HIV/HBV coinfection are limited **(BII)**. Due to safety concerns, peginterferon alfa should not be used in HIV/HBV-coinfected persons with cirrhosis.

- **Need to discontinue medications active against HBV:** The patient's clinical course should be monitored with frequent liver function tests. The use of adefovir dipivoxil, entecavir, or telbivudine to prevent flares, especially in patients with marginal hepatic reserve such as persons with compensated or decompensated cirrhosis, can be considered *[8]*. These alternative HBV regimens should only be used in addition to a fully suppressive ARV regimen.

- **Need to change ART because of HIV resistance:** If the patient has adequate HBV suppression, the ARV drugs active against HBV should be continued for HBV treatment in combination with other suitable ARV agents to achieve HIV suppression **(AIII)**.

HEPATITIS C (HCV)/HIV COINFECTION (Updated December 1, 2009)

Long-term studies of patients with chronic hepatitis C virus (HCV) infection show that approximately 33% of the patients progress to cirrhosis at a median time of less than 20 years *[1-2]*. This rate of progression increases with older age, alcoholism, male sex, and HIV infection *[3-6]*. A meta-analysis demonstrated that the rate of progression to cirrhosis for persons coinfected with HCV/HIV was about three times higher than the rate for HCV mono-infected patients *[5]*. This accelerated rate is magnified in patients with low CD4 counts. Chronic HCV infection also complicates HIV treatment due to the increased frequency of antiretroviral (ARV)-associated hepatotoxicity *[7-8]*. Multiple studies have shown poor prognosis for HCV/HIV coinfection in the era of combination antiretroviral therapy (ART). It is unclear if HCV infection accelerates the rate of HIV progression *[9]* or if the accelerated rate primarily reflects the impact of injection drug use, which is strongly linked to HCV infection *[10-11]*. Although whether ART reduces the attributable morbidity/mortality from untreated HCV is unknown, the presence of chronic HCV infection influences the treatment of HIV with ARV as discussed below.

Assessment of HCV/HIV Coinfection Prior to Antiretroviral Therapy

- Prior to initiation of ART, HIV-infected patients should be screened for HCV infection with sensitive immunoassays licensed for detection of antibody to HCV in blood. To confirm the presence of chronic infection, HCV-seropositive persons should be tested for HCV RNA using a qualitative or quantitative assay *[12]*.
- Patients with HCV/HIV coinfection should be advised to avoid alcohol consumption, use appropriate precautions to prevent transmission of both viruses to others, and receive hepatitis A (HAV) and hepatitis B (HBV) vaccines if susceptible.
- All patients with HCV/HIV coinfection should be evaluated for HCV therapy. HCV treatment is recommended according to standard guidelines with strong preference for treating patients with higher CD4 counts. For patients with lower CD4 counts (<200 cells/mm^3), it may be preferable to initiate ART and delay HCV therapy until CD4 counts increase as a result of HIV treatment *[12-15]*.
- Concurrent treatment of both HIV and HCV is feasible but may be complicated by pill burden, drug toxicities, and drug interactions. Some notable considerations include:
    - Didanosine (ddI) should not be given with ribavirin because of the potential for drug-drug interactions leading to life-threatening ddI-associated mitochondrial toxicity including hepatomegaly/steatosis, pancreatitis, and lactic acidosis *[16]*.
    - Zidovudine (ZDV) combined with ribavirin should be avoided when possible because the higher rates of anemia associated with the combination make ribavirin dose reduction necessary *[17]*.
    - Abacavir (ABC) has been associated with decreased response to peginterferon plus ribavirin in some, but not all, retrospective studies; current evidence is insufficient to recommend avoiding this combination *[18-20]*.
    - Growth factors (e.g., filgrastim and erythropoietin) may be required to manage interferon-associated neutropenia and ribavirin-associated anemia; ZDV may increase the need for adjuvant growth factors due to increased bone marrow suppression *[17]*.

Antiretroviral Therapy in HCV/HIV Coinfection

- Hepatotoxicity: Drug-induced liver injury (DILI) following ART is more common in HIV/HCV coinfection. The greatest risk of DILI may be observed in coinfected persons with advanced liver disease (e.g., cirrhosis or end-stage liver disease) *[21]*. Eradication of HCV infection may decrease the likelihood of ARV-associated DILI *[22]*.
    - Given the substantial heterogeneity in patient populations and drug regimens, comparison of DILI incidence rates for individual ARV agents across clinical trials is difficult. In such studies, the highest incidence rates of Grade 3 or 4 elevations in liver enzyme levels have been observed during therapy with ARV drugs that are no longer commonly used in clinical practice and that include stavudine (d4T) (with or without ddI), nevirapine (NVP), full-dose ritonavir (RTV) (600 mg twice daily), or tipranavir (TPV) (boosted by low-dose RTV) *[23]*. Also, due to the potential for concurrent fatty liver disease (steatosis), the use of d4T or ddI should be limited *[24]*.
    - Patients should be monitored by following alanine aminotransferase (ALT) and aspartate aminotransferase (AST) levels at 1 month and then every 3 months after initiation of ART. Mild to moderate fluctuations in ALT and/or AST are typical in persons with chronic HCV infection. In the

absence of signs and/or symptoms of liver disease these fluctuations do not require interruption of ART. Significant ALT and/or AST elevation (>5 times the upper limit of the laboratory reference range) should prompt careful evaluation for signs and symptoms of liver insufficiency and for alternative causes of liver injury (e.g., acute HAV or HBV infection, hepatobiliary disease, or alcoholic hepatitis); short-term interruption of ART may be required *[25]*.

- When to start ART: The rate of liver disease (fibrosis) progression is accelerated by HIV/HCV coinfection, particularly in persons with low CD4 counts (≤350 cells/mm^3). Data derived largely from retrospective cohort studies regarding the effect of ART on the natural history of HCV disease are inconsistent *[6, 26-27]*. However, ART may slow the progression of liver disease by preserving or restoring immune function and reducing HIV-related immune activation and inflammation *[28-30]*. Thus, for most coinfected patients including those with cirrhosis, the potential benefits of ART outweigh concerns regarding DILI.
    - ART should be started in HCV/HIV-coinfected persons in accordance with the Panel's recommendation for initiating ART in ART-naïve patients.

- What to start and what not to use: Initial combination regimens for the ARV-naïve patient with HCV/HIV are the same as for persons without HCV infection. HCV infection does not significantly alter the virologic or immunologic response to effective ART *[31]*. Special considerations for ART in persons with HCV/HIV coinfection include:
    - Patients receiving or considering therapy with ribavirin should avoid ddI, d4T, and ZDV.
    - ARV agents with the greatest risk of DILI should be used with caution.
    - Cirrhotic patients should be carefully assessed for signs of liver decompensation according to the Child-Turcotte-Pugh classification system because hepatically metabolized ARV drugs may require dose modification or avoidance in patients with Child-Pugh class B and C disease. (See **Appendix B, Table 7**.)

MYCOBACTERIUM TUBERCULOSIS DISEASE WITH HIV COINFECTION

(Updated January 10, 2011)

Panel's Recommendations:

- ***The treatment of active tuberculosis (TB) disease in patients with HIV infection should follow the same principles for persons without HIV infection (AI).***
- ***All HIV-infected patients with diagnosed active TB should be started on TB treatment immediately (AI).***
- ***All HIV-infected patients with diagnosed active TB should be treated with antiretroviral therapy (ART) (AI).***
- ***For patients with CD4 count <200 cells/mm^3, ART should be initiated within 2–4 weeks of starting TB treatment (AI).***
- ***For patients with CD4 count 200–500 cells/mm^3, the Panel recommends initiation of ART within 2–4 weeks, or at least by 8 weeks after commencement of TB therapy (AIII).***
- ***For patients with CD4 count >500 cells/mm^3, most Panel members also recommend starting ART within 8 weeks of TB therapy (BIII).***
- ***Despite pharmacokinetic drug interactions, a rifamycin should be included in regimens for patients receiving ART, with dosage adjustment if necessary (AII).***
- ***If a protease inhibitor (PI)-based regimen is used, rifabutin is the preferred rifamycin in HIV-infected patients with active TB disease due to its lower risk of substantial interactions with PIs (AII). Coadministration of rifampin and PIs (with or without ritonavir [RTV] boosting) is not recommended (AII).***
- ***Immune reconstitution inflammatory syndrome (IRIS) may occur after initiation of ART. Both ART and TB treatment should be continued while managing IRIS (AIII).***
- ***Treatment support, including directly observed therapy (DOT) of TB treatment, is strongly recommended for HIV-infected patients with active TB disease (AII).***

Rating of Recommendations: A = Strong; B = Moderate; C = Optional
Rating of Evidence: I = data from randomized controlled trials; II = data from well-designed nonrandomized trials or observational cohort studies with long-term clinical outcomes; III = expert opinion

Terminology: In this section, the terms "HIV-infected with active TB disease" and "HIV/TB disease" are used synonymously to designate HIV-infected patients with active TB disease in need of TB treatment. "HIV/TB coinfection" is not used because the term can refer to either active TB or latent TB infection (LTBI) in the presence of HIV infection and may cause confusion.

Treatment of Active TB in HIV Patients

HIV infection significantly increases the risk of progression from latent to active TB disease. The CD4 cell count influences both the frequency and severity of active TB disease *[1-2]*. Active TB also negatively affects HIV disease. It may be associated with a higher HIV viral load and more rapid progression of HIV disease *[2-3]*.

Active pulmonary or extrapulmonary TB disease requires prompt initiation of TB treatment. The treatment of active TB disease in HIV-infected patients should follow the general principles for persons without HIV (**AI**). Treatment of drug-susceptible TB disease should include a standard regimen that consists of isoniazid (INH) + a rifamycin (rifampin or rifabutin) + pyrazinamide + ethambutol given for 2 months, followed by INH + a rifamycin for 4 to 7 months *[4]*. A more complete discussion of the diagnosis and treatment of TB disease and LTBI in HIV patients is available in the ***Guidelines for Preventing and Treating Opportunistic Infections in HIV-Infected Adults and Adolescents*** *[4]*.

All patients with HIV/TB disease should be treated with ART **(AI)**. Important issues related to the use of ART in patients with active TB disease include: (1) when to start ART, (2) significant pharmacokinetic drug interactions with rifamycins, (3) the additive toxicities associated with ARV and TB drugs, (4) the development of IRIS with TB after

ART initiation, and (5) the need for treatment support including DOT and the integration of HIV and TB care and treatment.

When to Start Antiretroviral Therapy

Patients Diagnosed with TB While Receiving ART

At the time TB treatment is initiated in patients receiving ART, the patient's ARV regimen should be assessed with particular attention to potential pharmacokinetic interactions with rifamycins (discussed below). The patient's regimen may need to be modified to permit use of the optimal TB treatment regimen.

Patients Receiving Treatment for Active TB but Not Yet on ART

When to initiate ART in patients with active TB has been the subject of differing recommendations based upon observational studies and expert opinion *[4-6]*. Two randomized controlled trials now provide some additional evidence regarding this issue. In these studies, concomitant administration of therapy for both TB disease and HIV infection resulted in significant reduction in HIV/TB disease mortality *[7-8]*. The results of an ACTG trial will soon be available and may provide further guidance or support for recommendations concerning when to start ART in patients with active TB.

In the SAPIT study from South Africa, HIV-infected patients with smear-positive TB and CD4 counts <500 cells/mm^3 were randomized to one of three treatment arms: integrated therapy with ART initiated either during the first 4 weeks of TB therapy or after the second month (i.e., during the continuation phase of TB therapy) or sequential therapy with ART initiated after the conclusion of standard TB therapy. The sequential arm was stopped when an early analysis demonstrated a 55% reduction in mortality in the combined two integrated arms compared with the sequential therapy arm *[7]*. In the CAMELIA study from Cambodia *[8]*, patients with CD4 counts <200 cells/mm^3 were randomized to initiate ART at 2 weeks or at 8 weeks of TB treatment. A 34% reduction in mortality was seen with ART initiation at 2 weeks compared with initiation at 8 weeks ($p = 0.002$). The populations in these two studies differed: the median CD4 count among SAPIT participants was 140–150 cells/mm^3; in the CAMELIA trial, the median CD4 count at entry was 25 cells/mm^3. Low CD4 count at study baseline predicted poorer survival in both studies. Both studies demonstrated excellent ART response: 90% and >95% of participants achieved suppressed HIV RNA (<400 copies/mL) at 12 months in the SAPIT study and CAMELIA trial, respectively. Although in both studies IRIS was more common in patients initiating ART earlier, the syndrome was not associated with mortality.

Based on the available data and the potential benefits of ART in patients with active TB, the Panel recommends the following:

- ***For patients with CD4 count <200 cells/mm^3, ART should be initiated within 2–4 weeks of starting TB treatment (AI).***
- ***For patients with CD4 count 200–500 cells/mm^3, the Panel recommends initiation of ART within 2–4 weeks, or at least by 8 weeks after commencement of TB therapy (AIII).***
- ***For patients with CD4 count >500 cells/mm^3, most Panel members also recommend starting ART within 8 weeks of TB therapy (BIII).***

ART should be started as early as feasible for all HIV-infected pregnant women with active TB, both for maternal health and for prevention of mother-to-child transmission (PMTCT) of HIV **(AIII)**. An augmented immune or inflammatory response in patients with some manifestations of TB, such as meningitis, pericarditis, or respiratory failure, might be life threatening. In these circumstances, delaying initiation of ART briefly beyond recommended intervals may be appropriate **(CIII)**.

Drug Interaction Considerations

A rifamycin is a crucial component for the treatment of drug-sensitive TB. However, both rifampin and rifabutin are inducers of the hepatic cytochrome P (CYP) 450 and uridine diphosphate gluconyltransferase (UGT) 1A1 enzymes and are associated with interactions with most ARV agents including all PIs, non-nucleoside reverse transcriptase

inhibitors (NNRTIs), maraviroc (MVC), and raltegravir (RAL). Rifampin is a strong enzyme inducer, leading to enhanced drug clearance and greater reduction in ARV drug exposure. Rifabutin, a weaker enzyme inducer, is an alternative to rifampin. Because rifabutin is a substrate of the CYP 450 enzyme system, its metabolism may be affected by the NNRTI or PI as discussed below. **Tables 15a and 15b** outline the magnitude of these interactions and provide dosing recommendations when rifamycins and selected ARV drugs are used concomitantly. After determining the drugs and doses to use, patients should be closely monitored to assure good control of both TB and HIV. Suboptimal HIV suppression or suboptimal response to TB treatment should prompt assessment of drug adherence, subtherapeutic drug levels (consider therapeutic drug monitoring [TDM]), and acquired drug resistance.

Rifamycins and NNRTIs

Rifampin induces metabolism of both nevirapine (NVP) *[9]* and efavirenz (EFV) *[10]* leading to reduced NNRTI drug exposure. The extent of induction is less pronounced with EFV than with NVP. Despite the interactions, some observational studies suggest that good virologic, immunologic, and clinical outcomes may be achieved with standard doses of either EFV *[11-12]* or NVP *[13-14]* when combined with rifampin.

Rifabutin does not significantly affect EFV and NVP drug exposure. Because both EFV and NVP can induce rifabutin metabolism, an increased rifabutin dose is recommended. Few data exist on the use of rifampin and etravirine (ETR); however, because rifampin is expected to induce ETR metabolism, concomitant use is not recommended. Rifabutin is recommended in this situation.

Rifamycins and PIs

Rifampin can significantly decrease PI drug exposure, despite ritonavir (RTV) boosting, with resultant risk of ART failure *[15-16]*. Some investigators had explored the use of an additional RTV dose or doubling PI doses in attempt to overcome rifampin's induction effect. However, a high rate of serious hepatotoxicity and significant gastrointestinal intolerance resulted in terminations of these studies *[15, 17-18]*. Therefore, coadministration of rifampin and PIs is **not recommended** (**AII**).

Because rifabutin has a less significant impact on the pharmacokinetics of RTV-boosted PIs, it is the preferred rifamycin to use with PI-based regimens **(AII)**. Both RTV-boosted and -unboosted PIs can inhibit rifabutin metabolism and the optimal dose of rifabutin is yet to be defined. Most PI manufacturers suggest rifabutin 150 mg every other day (instead of normal doses of 300 mg once daily). Lower than expected drug exposure *[19-20]* and acquired rifamycin resistance have been reported in HIV-infected patients who received PI-based regimens and intermittent doses of rifabutin *[19, 21]*. If available, TDM can be helpful in assessing the adequacy of rifabutin drug exposure.

Rifamycins and MVC or RAL

MVC is a substrate of CYP3A4 and rifampin can significantly reduce MVC concentration. If concomitant use is necessary, the MVC dose should be increased. Rifabutin may be an alternative rifamycin. (See **Table 15d** for recommended doses of MVC used with rifamycins.)

Rifampin, a strong UGT1A1 enzyme inducer, significantly accelerates the metabolism of RAL *[22]*. When used in combination with rifampin, the RAL dose should be increased to 800 mg twice daily. Rifabutin has minimal effect on RAL metabolism and may be more appropriate in this situation.

Anti-TB/ARV Toxicities

ARV agents and TB drugs, particularly INH, rifamycin, and pyrazinamide, can cause drug-induced hepatitis. These first-line TB drugs should still be used for treatment of active TB disease, even with coadministration of other potentially hepatotoxic drugs or in the presence of baseline liver disease **(AIII)**. Patients receiving drugs with potential hepatotoxicity should have frequent monitoring for clinical symptoms and signs of hepatitis and laboratory monitoring for hepatotoxicity. Peripheral neuropathy can occur with INH, didanosine (ddI), or stavudine (d4T) or may be a manifestation of HIV. All patients receiving INH should also receive supplemental pyridoxine to reduce peripheral

neuropathy. Patients should be monitored closely for signs of drug-related toxicities and receive alternatives to ddI or d4T.

IRIS with TB and ARV Agents

IRIS occurs in two forms, "unmasking" and "paradoxical." The mechanism is the same for both forms of IRIS: restoration of immune competence by administration of ARV agents, resulting in an exuberant host response to TB bacilli and/or antigens. Unmasking IRIS refers to the initial clinical expression of active TB occurring soon after ARV agents are started. Paradoxical IRIS refers to the worsening of TB clinical manifestations after ARV agents are started in patients who are receiving TB treatment. Severity of IRIS ranges from mild to severe to life threatening. IRIS has been reported in 8% to greater than 40% of patients starting ART after TB is diagnosed, although the incidence depends on the definition of IRIS and the intensity of monitoring *[23-24]*.

Predictors of IRIS include CD4 count <50 cells/mm^3, higher on-ART CD4 counts, high pre-ART and lower on-ART HIV viral loads, severity of TB disease, especially high pathogen burden, and less than 30-day interval between initiation of TB and HIV treatments. *[5, 25-29]*. Most IRIS in HIV/TB disease occurs within 3 months of the start of TB treatment. Delaying the start of ART for 2–8 weeks may reduce the incidence and severity of IRIS but must be weighed against the potential benefit of earlier ART in improving immune function and preventing progression of HIV disease and mortality.

Milder or moderately severe cases of IRIS can be managed symptomatically or treated with nonsteroidal inflammatory agents. More severe cases can be successfully treated with corticosteroids. A recent randomized, placebo-controlled trial demonstrated benefit of corticosteroid treatment as measured by decreasing days of hospitalization and Karnofsky performance score without adverse consequences *[30]*. In the presence of IRIS, neither TB therapy nor ART should be stopped because both therapies are necessary for the long-term health of the patient **(AIII)**.

Immune Reconstitution with ART: Conversion to Positive Tuberculin Skin Test (TST) and Interferon-Gamma (IFN-γ) Release Assay (IGRA)

Immune reconstitution with ART may result in unmasking LTBI (i.e., conversion of a previously negative TST to a positive TST or a positive IGRA for *Mycobacterium tuberculosis*-specific proteins). A positive IGRA, similar to a positive TST, is indicative of LTBI in the absence of evidence of active TB disease *[31]*. Because treatment for LTBI is indicated in the absence of evidence of active TB disease, clinicians should be aware of this phenomenon. Patients with a negative TST or IGRA and advanced HIV disease (i.e., CD4 count <200 cells/mm^3) should have a repeat TST or IGRA after initiation of ART and CD4 count increase to >200 cells/mm^3 *[32]* **(BII)**.

Caring for Patients with HIV and TB

Integration of diagnosis and treatment and/or close collaboration between TB and HIV clinicians, health care institutions, and public health programs are necessary in order to improve medication adherence and TB treatment completion rates, reduce toxicities, and maximize HIV outcomes in HIV-infected patients with active TB disease *[4]*. These patients should receive treatment support, including adherence counseling and DOT, corresponding to their needs **(AII)**. ART simplification or use of coformulated fixed-dose combinations may also be helpful to improve drug adherence.

Limitations to Treatment Safety and Efficacy

ADHERENCE TO ANTIRETROVIRAL THERAPY (Updated November 3, 2008)

Adherence to antiretroviral therapy (ART) has been strongly correlated with HIV viral suppression, reduced rates of resistance, an increase in survival, *and* improved quality of life *[1-2]*. Because HIV treatment is a lifelong endeavor, and because many patients will initiate therapy when they are generally in good health, feel well, and demonstrate no obvious signs or symptoms of HIV disease, adherence poses a special challenge and requires commitment from the patient and the health care team. This section of the guidelines provides clinicians with a basis to approach the challenging and complicated topic of adherence.

Predictors of Adherence

Adherence is related to characteristics of the patient, the regimen, the clinical setting, and the relationship of the provider and the patient *[3]*. To assure adherence, it is critical that the patient receive and understand information about HIV disease and the specific regimen prescribed. A number of factors have been associated with poor adherence, including the following:

- low levels of literacy *[4]*;
- certain age-related challenges (e.g., vision loss, cognitive impairment) *[5]*;
- psychosocial issues (e.g., depression, homelessness, inadequate social support, stressful life events, dementia, or psychosis) *[6]*;
- active (but not history of) substance abuse, particularly for patients who have experienced recent relapse;
- stigma *[7];*
- difficulty taking medication (e.g., trouble swallowing pills, daily schedule issues);
- complex regimens (e.g., pill burden, dosing frequency, food requirements);
- adverse drug effects; and
- treatment fatigue.

Adherence studies in the early era of combination ART with unboosted protease inhibitors (PIs) found that taking 95% or more of doses was required for full viral suppression *[8]*. More recent adherence studies that utilized boosted PIs and non-nucleoside reverse transcriptase inhibitors (NNRTIs) suggest that boosted PIs and efavirenz (EFV) may be more forgiving of lapses in adherence because of their longer half-lives *[9-10]*. Nonetheless, clinicians should encourage patients to adhere as closely as possible to the prescribed doses for all antiretroviral (ARV) regimens.

Measurement of Adherence

There is no gold standard for the assessment of adherence *[1]*, but there are many validated tools and strategies to choose from. Although patient self-report of adherence predictably overestimates adherence by as much as 20% *[11]*, this measure still is associated with viral load responses *[12]*. Thus, a patient's report of suboptimal adherence is a strong indicator of nonadherence and should be taken seriously.

When ascertained in a simple, nonjudgmental, routine, and structured format that normalizes less-than-perfect adherence and minimizes socially desirable responses, patient self-report remains the most useful method for the assessment and longitudinal monitoring of a patient's adherence in the clinical setting. A survey of all doses during the past 3 days or the past week accurately reflects longitudinal adherence and is the most practical and readily available tool for adherence assessments in clinical trials and in clinical practice *[1]*. Other strategies may also be effective. One study found that asking patients to rate their adherence on a six-point scale during 1 month was more accurate than asking them how often they miss doses or asking about the percentage of doses taken during the previous 3 or 7 days *[13]*. Pharmacy records and pill counts also can be used as an adjunct to simply asking the patient *[14]*. Other methods of assessing adherence include the use of electronic measurement devices (e.g., bottle caps, dispensing systems). However, these methods may not be feasible in some clinical settings.

Interventions to Improve Adherence

Prior to writing the first prescriptions, the clinician should assess the patient's readiness to take medication, factors that might limit adherence (psychiatric illness, active drug use, etc.) that may require additional support, understanding of the disease and the regimen, social support, housing, work and home situation, and daily schedules. Patients should understand that the first regimen is usually the best chance for a simple regimen with long-term treatment success and prevention of drug resistance. Resources individualized to each patient's schedule, competing psychosocial needs, learning needs, and literacy level should be identified to foster adherence.

Individualizing treatment with involvement of the patient in decision making is the cornerstone of any treatment plan *[14]*. The first principle of successful treatment is negotiation of an understandable plan to which the patient can commit *[15-16]*. Establishing a trusting relationship over time and maintaining good communication will help to improve adherence and long-term outcomes. With the patient who is not critically ill, several office visits and the patience of clinicians are generally required before therapy can be started.

A growing menu of possible interventions has demonstrated efficacy in improving adherence toART. For example, a meta-analysis of 19 randomized controlled trials of ARV adherence interventions found that intervention participants were 1.5 times as likely to report 95% adherence and 1.25 times as likely to achieve an undetectable viral load compared with participants in comparison conditions *[17]*. Interventions that have been successful include those focused on the patient and those that work to improve the tolerability of the regimen. Successful support interventions of different modalities have included the following: adherence support groups, peer adherence counselors, behavioral interventions, cognitive-behavioral and reminder strategies, and use of community-based case managers and peer educators. Health care team members, such as nurses, nurse practitioners, pharmacists, medication managers, and social workers, have integral roles in successful adherence programs *[18-21]*. It is also important to address the competing needs of a patient, including active substance use, depression, and housing issues, to reduce the risk of nonadherence.

A number of advances during the past several years have dramatically simplified many regimens, particularly for ART-naïve patients. Prescribing regimens that are simple to take, have a low pill burden and frequency of dosing, have no food requirements, and have low incidence and severity of adverse effects will facilitate adherence. Current treatment recommendations take regimen simplicity as well as efficacy into account.

Adherence assessment and counseling should be done at each clinical encounter and should be the responsibility of the entire health care team. Directly observed therapy (DOT) has been shown to be effective in provision of ART to active drug users *[22]*. In resource-limited settings, the use of community-based DOT has been very successful, and programs have replicated this intervention with success in the United States *[23]*. Although DOT is labor intensive and programmatically complex, modification of traditional DOT methodologies may be feasible and can be adapted in a variety of clinical settings, in which DOT is given a few days each week *[24]*.

Conclusion

Significant progress has been made regarding determinants, measurements, and interventions to improve adherence to ART. Given the various assessment strategies and potential interventions available, the challenge for the treatment team is to select the techniques that provide the best fit for their treatment setting, resources, and patient population. The complexity of this topic and the importance of adherence encourage clinicians to continue to seek novel, patient-centered ways to prevent nonadherence and to tailor adherence interventions. Early detection of nonadherence and prompt intervention can greatly reduce the development of viral resistance and the likelihood of virologic failure.

Table 12. Strategies to Improve Adherence to Antiretroviral Therapy

Strategies	Examples
Use a multidisciplinary team approach Provide an accessible, trusting health care team	• Nurses, social workers, pharmacists, and medication managers
Establish a trusting relationship with the patient	
Establish readiness to start ART	
Identify potential barriers to adherence prior to starting ART	• Psychosocial issues • Active substance abuse or at high risk of relapse • Low literacy level • Busy daily schedule and/or travel away from home • Lack of disclosure of HIV diagnosis • Skepticism about ART • Lack of prescription drug coverage
Provide resources for the patient	• Referrals for mental health and/or substance abuse treatment • Resources to obtain prescription drug coverage • Pillboxes
Involve the patient in antiretroviral (ARV) regimen selection	• For each option, review potential side effects, dosing frequency, pill burden, storage requirements, food requirements, and consequences of nonadherence
Assess adherence at every clinic visit	• Use a simple checklist the patient can complete in the waiting room • Have other members of the health care team also assess adherance • Ask the patient open-ended questions (e.g., *In the last 3 days, please tell me how you took your medicines.*)
Identify the type of nonadherence	• Failure to fill the prescription(s) • Failure to take the right dose(s) at the right time(s) • Nonadherence to food requirements
Identify reasons for nonadherence	• Adverse effects from medications • Complexity of regimen (pill burden, dosing frequency, etc.) • Difficulty swallowing large pills • Forgetfulness • Failure to understand dosing instructions • Inadequate understanding of drug resistance and its relationship to adherence • Pill fatigue • Other potential barriers (see list above)
Assess and simplify regimen, if possible

ADVERSE EFFECTS OF ANTIRETROVIRAL AGENTS (Updated January 10, 2011)

Adverse effects have been reported with all antiretroviral (ARV) drugs and are among the most common reasons for switching or discontinuing therapy as well as for medication nonadherence *[1]*. Rates of treatment-limiting adverse events in antiretroviral therapy (ART)-naïve patients enrolled in randomized trials appear to be declining with newer ARV regimens and are generally now less than 10%. However, most clinical trials have a relatively short follow-up duration and can underestimate longer term complications of therapy. In the Swiss Cohort study, the presence of laboratory adverse events was associated with higher rates of mortality during 6 years of follow-up, highlighting the importance of adverse events in overall patient management *[2]*.

Several factors may predispose individuals to adverse effects of ARV medications. For example, women seem to have a higher propensity of developing Stevens-Johnson syndrome, rashes, and hepatotoxicity from nevirapine (NVP) (ART-naïve women with CD4 counts >250 cells/mm^3) *[3-5]* as well as higher rates of lactic acidosis from nucleoside reverse transcriptase inhibitors (NRTIs) *[6-8]*. Other factors may also contribute to the development of adverse events: concomitant use of medications with overlapping and additive toxicities; comorbid conditions that may increase the risk of or exacerbate adverse effects (e.g., alcoholism *[9]* or coinfection with viral hepatitis, which may increase risk of hepatotoxicity *[10-12]*); drug-drug interactions that may lead to an increase in dose-related toxicities (e.g., concomitant use of ribavirin with didanosine [ddI], which may increase ddI-associated toxicities) *[13-15]*); or genetic factors predisposing patients to abacavir (ABC) hypersensitivity reaction *[16-17]*.

Although the therapeutic goals of ART include achieving and maintaining viral suppression and improving patient immune function, an overarching goal should be to select a regimen that not is only effective but also is safe. This requires consideration of not only the toxicity potential of an ARV regimen but also an individual patient's underlying conditions, concomitant medications, and history of drug intolerance.

Information on adverse events is outlined in multiple tables in the guidelines:

Table 13 provides clinicians with a list of the most common and/or severe known ARV-associated adverse events listed by drug class. **Appendix B, Tables 1–6** summarize the most common adverse effects of individual ARV agents. Some approaches to the management of complications of ART have been published and will not be discussed in these tables *[18-21]*.

Table 13. Antiretroviral Therapy-Associated Common and/or Severe Adverse Effects (January 10, 2011)

(See Appendix B for additional information listed by drug.)

Adverse Effects	NRTIs	NNRTIs	PIs	INSTI	EI
Bleeding events			**All PIs:** ↑ spontaneous bleeding, hematuria in hemophilia **TPV:** Reports of intracranial hemorrhage. Risks include CNS lesions; trauma; surgery; hypertension; alcohol abuse; coagulopathy, anti-coagulant, or anti-platelet agents including vitamin E		
Bone marrow suppression	**ZDV:** Anemia, neutropenia				
Cardiovascular disease (CVD)	**ABC** and **ddI:** Associated with myocardial infarction (MI) in some but not all cohort studies. Risk greatest among those with traditional CVD risk factors.		**PIs:** Associated with MI and stroke in some cohort studies. Risk greatest among those with traditional CVD risk factors. Limited data on newer PIs (ATV, DRV, TPV). **SQV/r**, **ATV/r,** and **LPV/r:** PR interval prolongation. Risks include structural heart disease, conduction system abnormalities, cardiomyopathy, ischemic heart disease, and coadministration with drugs that prolong PR interval. **SQV/r:** QT interval prolongation in a healthy volunteer study. Risks include underlying heart conditions, pre-existing prolonged QT or arrhythmia, or use with other QT-prolonging drugs. ECG prior to SQV initiation is recommended and should be considered during therapy.		
Central nervous system (CNS) effects	**d4T:** Associated with rapidly progressive ascending neuromuscular weakness resembling Guillain-Barré syndrome (rare)	**EFV:** Somnolence, insomnia, abnormal dreams, dizziness, impaired concentration, depression, psychosis, suicidal ideation. Most symptoms subside or diminish after 2–4 weeks. Bedtime dosing may reduce symptoms. Risks include history of psychiatric illness, concomitant use of agents with neuropsychiatric effects, and ↑ plasma EFV concentrations due to genetic factors or absorption (i.e., with food).			
Diabetes mellitus (DM)/insulin resistance	**ZDV, d4T,** and **ddI**		• Reported for some **PIs (IDV, LPV/r)**, but not all PIs studied • **ATV** +/- **RTV** not found to alter insulin sensitivity		
Dyslipidemia	**d4T > ZDV > ABC:** •↑ LDL and TG	**EFV** •↑TG •↑LDL •↑HDL	↑LDL, ↑TG, ↑HDL: **all RTV-boosted PIs** ↑TG: **LPV/r** = **FPV/r** and **LPV/r** > **DRV/r** and **ATV/r**		
Gastrointestinal (GI)	Nausea and vomiting: **ddI** and **ZDV** > other **NRTIs** Pancreatitis: **ddI**		GI intolerance (diarrhea, nausea, vomiting) Diarrhea: common with **NFV**. **LPV/r** > **DRV/r** and **ATV/r**		

Adverse Effects	NRTIs	NNRTIs	PIs	INSTI	EI
Hepatic effects	Reported for most **NRTIs** **ddI:** prolonged exposure linked to noncirrhotic portal hypertension, some cases with esophageal varicees Steatosis: most commonly seen with **ZDV**, **d4T**, or **ddI** Flares: hepatitis B virus (HBV)-coinfected patients may develop severe hepatic flare when **TDF**, **3TC**, and **FTC** are withdrawn or when HBV resistance develops.	**NVP > other NNRTIs** **NVP:** • Severe hepatic toxicity with **NVP** is often associated with skin rash or symptoms of hypersensitivity. • For ARV-naïve patients, risk is greater for women with pre-**NVP** CD4 count >250 cells/mm^3 and men with pre-**NVP** CD4 count >400 cells/mm^3. Risk is higher for women. • 2-week dose escalation of **NVP** reduces risk of rash and possibly hepatotoxicity if related to hypersensitivity. • Given high risk in those with competent immune systems, **NVP** should never be used for post-exposure prophylaxis in HIV-uninfected individuals. • **NVP** is contraindicated in patients with Child-Pugh classification B or C.	**All PIs:** Drug-induced hepatitis and hepatic decompensation (and rare cases of fatalities) have been reported with all PIs to varying degrees. **TPV/r** has a higher frequency of hepatic events than other PIs. **IDV, ATV**: jaundice due to indirect hyperbilirubinemia **TPV/r:** Contraindicated in patients with moderate to severe hepatic insufficiency (Child-Pugh classification B or C)		
Hypersensitivity reaction (HSR) (excluding rash alone or Stevens Johnson syndrome[SJS])	**ABC**: • HLA-B*5701 screening prior to initiation of **ABC**. Should not be started if HLA-B*5701 is positive. • Symptoms of HSR include (in descending frequency): fever, skin rash, malaise, nausea, headache, myalgia, chills, diarrhea, vomiting, abdominal pain, dyspnea, arthralgia, respiratory symptoms • Worsen with continuation of **ABC** • Median onset 9 days; ~ 90% of reactions within first 6 weeks • Onset of rechallenge reactions is within hours of rechallenge dose	**NVP**: • Hypersensitivity syndrome of hepatic toxicity and rash that may be accompanied by fever, general malaise, fatigue, myalgias, arthralgias, blisters, oral lesions, conjunctivitis, facial edema, eosinophilia, granulocytopenia, lymphadenopathy, or renal dysfunction. • For ARV-naïve patients, risk is greater for women with pre-**NVP** CD4 count >250 cells/mm^3 and men with pre-**NVP** CD4 count >400 cells/mm^3. Risk is higher for women. • 2-week dose escalation of **NVP** reduces risk.			
Lactic acidosis	**NRTIs,** especially **d4T, ZDV,** and **ddI** • Insidious onset with GI prodrome, weight loss, and fatigue. May be rapidly progressive, with tachycardia, tachypnea, jaundice, muscular weakness, mental status changes, respiratory distress, pancreatitis, and organ failure. • Mortality up to 50% in some case series, especially in patients with serum lactate >10 mmol/L • Increased risk: female sex, obesity Laboratory findings: • ↑ lactate (often >5 mmol/L), anion gap, AST, ALT, PT, bilirubin • ↑ amylase and lipase in patients with pancreatitis • ↓ arterial pH, serum bicarbonate, serum albumin				

Adverse Effects	NRTIs	NNRTIs	PIs	INSTI	EI
Lipodystrophy	Lipoatrophy: **Thymidine analogs (d4T > ZDV).** May be more likely when combined with **EFV** vs. **boosted PI**.	Lipohypertophy: Trunk fat increase observed with **EFV**-, **PI**-, and **RAL**-containing regimens; however, causal relationship has not been established.			
Myopathy/elevated CPK	**ZDV:** myopathy			**RAL:** ↑ CPK. muscle weakness and rhabdomyolysis	
Nephrotoxicity/ urolithiasis	**TDF:** ↑ serum creatinine, proteinuria, hypophosphatemia, urinary phosphate wasting, glycosuria, hypokalemia, non-anion gap metabolic acidosis Concurrent use of **PI** may increase risk.		**IDV**: ↑ serum creatinine, pyuria; hydronephrosis or renal atrophy **IDV, ATV**: Stone, crystal formation; adequate hydration may reduce risk.		
Osteopenia/ osteoporosis	**TDF:** Associated with greater loss of bone mineral density (BMD) compared with **ZDV, d4T,** and **ABC.**	Decreases in BMD observed in studies of regimens containing different **NRTIs** combined with either **NNRTIs** or **PIs**.			
Peripheral neuropathy	Peripheral neuropathy (pain and/or paresthesias, lower extremities > upper extremities): **d4T > ddI** and **ddC** (can be irreversible) **d4T:** Associated with rapidly progressive ascending neuromuscular weakness resembling Guillain-Barré syndrome (rare)				
Rash		**All NNRTIs**	**ATV, DRV, FPV**		**MVC**
Stevens-Johnson syndrome (SJS/toxic epidermal necrosis (TEN)	**ddI, ZDV:** Reported cases	**NVP > DLV, EFV, ETR** For **NVP** risks include: •Female sex •Black, Asian, Hispanic race/ethnicity	**FPV, DRV, IDV, LPV/r, ATV:** Reported cases		

Acronyms:
Drug Classes: EI = entry inhibitor; INSTI = integrase strand transfer inhibitor; NNRTI = non-nucleoside reverse transcriptase inhibitor; NRTI = nucleoside reverse transcriptase inhibitor; PIs = protease inhibitor
Antiretroviral Drugs: 3TC = lamivudine; ABC = abacavir; ATV = atazanavir; ATV/r = atazanavir + ritonavir; d4T = stavudine; ddC = zalcitabine; ddI = didanosine; DLV = delaviridine; DRV = darunavir; DRV/r = darunavir + ritonavir; EFV = efavirenz; ETR = etravirine; FPV = fosamprenavir; FPV/r = fosamprenavir + ritonavir; FTC = emtricitabine; IDV = indinavir; LPV/r = lopinavir + ritonavir; MVC = maraviroc; NFV = nelfinavir; NVP = nevirapine; RAL = raltegravir; RTV = ritonavir; SQV/r = saquinavir + ritonavir; TDF = tenofovir; TPV = tipranavir; ZDV = zidovudine
Other: ALT = alanine aminotransferase; ARV = antiretroviral; AST = aspartate aminotransferase; BMD = bone mineral density; CNS = central nervous system; CPK = creatine phosphokinase; CVD = cardiovascular disease; DM = diabetes mellitus; ECG = electrocardiogram; GI = gastrointestinal; HBV = hepatitis B virus; HDL = high-density lipoprotein; HSR = hypersensitivity reaction; LDL = low-density lipoprotein; MI = myocardial infarction; PT = prothrombin time; SJS = Stevens-Johnson syndrome; TEN = toxic epidermal necrosis; TG = triglyceride

DRUG INTERACTIONS (Updated January 10, 2011)

Potential drug-drug and/or drug-food interactions should be taken into consideration when selecting an antiretroviral (ARV) regimen. A thorough review of current medications can help in designing a regimen that minimizes undesirable interactions. In addition, the potential for drug interactions should be assessed when any new drug, including over-the-counter agents, is added to an existing ARV combination. **Tables 14–16b** list significant drug interactions with different ARV agents and suggested recommendations on contraindications, dose modifications, and alternative agents.

Protease Inhibitors (PIs) and Non-Nucleoside Reverse Transcriptase Inhibitors (NNRTIs)

Most drug interactions with ARV drugs are mediated through inhibition or induction of hepatic drug metabolism *[1]*. All PIs and NNRTIs are metabolized in the liver by the cytochrome P (CYP) 450 system, particularly by the CYP3A4 isoenzyme. The list of drugs that may have significant interactions with PIs or NNRTIs is extensive and is continuously expanding. Some examples of these drugs include medications that are commonly prescribed in HIV-infected patients for non-HIV medical conditions, such as lipid-lowering agents (e.g., statins), benzodiazepines, calcium channel blockers, immunosuppressants (e.g., cyclosporine and tacrolimus), anticonvulsants, rifamycins, erectile dysfunction agents (e.g., sildenafil), ergot derivatives, azole antifungals, macrolides, oral contraceptives, and methadone. Herbal products, such as St. John's wort, can also cause interactions that risk adverse clinical effects.

All PIs are substrates of CYP3A4, so their metabolic rates may be altered in the presence of CYP inducers or inhibitors. Some PIs may also be inducers or inhibitors of other CYP isoenzymes and of P-glycoprotein or other transporters in the gut and elsewhere. Tipranavir (TPV), for example, is a potent inducer of CYP3A4 and P-glycoprotein. The net effect of tipranavir/ritonavir (TPV/r) on CYP3A *in vivo* appears to be enzyme inhibition. Thus, concentrations of drugs that are substrates for only CYP3A are likely to be increased if given with TPV/r. The net effect of TPV/r on a drug that is a substrate for both CYP3A and P-glycoprotein cannot be confidently predicted; significant decreases in saquinavir (SQV), amprenavir (APV), and lopinavir (LPV) concentrations have been observed *in vivo* when given with TPV/r.

The NNRTIs are also substrates of CYP3A4 and can act as an inducer (nevirapine [NVP]), an inhibitor (delavirdine [DLV]), or a mixed inducer and inhibitor (efavirenz [EFV]). Etravirine (ETR) is a substrate of CYPs 3A4, 2C9, and 2C19. It is also an inducer of CYP3A4 and an inhibitor of CYPs 2C9 and 2C19. Thus, these ARV agents can interact with each other in multiple ways and with other drugs commonly prescribed for other concomitant diseases.

The use of a CYP3A4 substrate that has a narrow margin of safety in the presence of a potent CYP3A4 inhibitor may lead to markedly prolonged elimination half-life ($t_{1/2}$) and toxic drug accumulation. Avoidance of concomitant use or dose reduction of the affected drug, with close monitoring for dose-related toxicities, may be warranted.

The inhibitory effect of ritonavir (RTV), however, can be beneficial when added to a PI, such as atazanavir (ATV), fosamprenavir (FPV), or indinavir (IDV) *[2]*. The PIs darunavir (DRV), LPV, SQV, and TPV require coadministration with RTV. Lower than therapeutic doses of RTV (100 to 400 mg per day) are commonly used in clinical practice as a pharmacokinetic enhancer to increase the trough concentration (C_{min}) and prolong the half-life of the active PIs *[3]*. The higher C_{min} allows for a greater C_{min}: inhibitory concentration (IC_{50}) ratio, which reduces the chance for development of drug resistance as a result of suboptimal drug exposure; the longer half-life allows for less frequent dosing, which may enhance medication adherence.

Coadministration of PIs or NNRTIs with a potent CYP3A4 inducer, on the other hand, may lead to suboptimal drug concentrations and reduced therapeutic effects of the ARV agents. These drug combinations should be avoided if alternative agents can be used. If this is not possible, close monitoring of plasma HIV RNA, with or without ARV dosage adjustment and therapeutic drug monitoring (TDM), may be warranted. For example, the rifamycins (i.e., rifampin and, to a lesser extent, rifabutin) are CYP3A4 inducers that can significantly reduce plasma concentrations of most PIs and NNRTIs *[4-5]*. Because rifabutin is a less potent inducer, it is generally considered a reasonable alternative to rifampin for the treatment of tuberculosis (TB) when it is used with a PI-based regimen, despite wider experience with rifampin use *[6]*. **Tables 15a and 15b** list dosage recommendations for concomitant use of rifamycins and other CYP3A4 inducers with PIs and NNRTIs.

Nucleoside Reverse Transcriptase Inhibitors (NRTIs)

Unlike PIs and NNRTIs, NRTIs do not undergo hepatic transformation through the CYP metabolic pathway. Some, however, do have other routes of hepatic metabolism. Significant pharmacodynamic interactions of NRTIs and other drugs have been reported. They include increases in intracellular drug levels and toxicities when didanosine (ddI) is used in combination with hydroxyurea *[7-8]* or ribavirin *[9]*, additive bone marrow suppressive effects of zidovudine (ZDV) and ganciclovir *[10]*, and antagonism of intracellular phosphorylation with the combination of ZDV and stavudine (d4T) *[11]*. Pharmacokinetic interactions have also been reported. However, the mechanisms of some of these interactions are still unclear. Examples of such interactions include increases of ddI concentration in the presence of tenofovir (TDF) *[12]* and decreases in ATV concentration when ATV is coadministered with TDF *[13]*. **Table 15c** lists significant interactions with NRTIs.

CCR5 Antagonist

Maraviroc (MVC), the first Food and Drug Administration (FDA)-approved CCR5 antagonist, is a substrate of CYP3A enzymes and P-glycoprotein. As a consequence, the concentrations of MVC can be significantly increased in the presence of strong CYP3A inhibitors (such as RTV and other PIs, except for TPV/r) and are reduced when used with CYP3A inducers (such as EFV or rifampin). Dose adjustment is necessary when MVC is used in combination with these agents. (See **Table 16b** or **Appendix B, Table 6** for dosage recommendations.) MVC is neither an inducer nor an inhibitor of the CYP3A system and does not alter the pharmacokinetics of the drugs evaluated in interaction studies to date.

Integrase Inhibitor

Raltegravir (RAL), an HIV integrase strand transfer inhibitor, is primarily eliminated by glucuronidation that is mediated by the uridine diphosphate (UDP)-glucuronosyltransferase (UGT) 1A1 enzymes. Strong inducers of UGT1A1 enzymes (e.g., rifampin) can significantly reduce the concentration of RAL *[14]*. (See **Table 15e** for dosage recommendations.) Other inducers of UGT1A1, such as EFV and TPV/r, can also reduce RAL concentration. A pharmacokinetic interaction should be considered if optimal virologic response is not achieved when these drugs are used in combination.

Fusion Inhibitor

The fusion inhibitor enfuvirtide (T-20) is a 36–amino acid peptide that does not enter human cells. It is expected to undergo catabolism to its constituent amino acids with subsequent recycling of the amino acids in the body pool. No clinically significant drug-drug interaction has been identified with T-20 to date.

1 DLV, IDV, and NFV are not included in this table. Refer to the FDA package insert for information regarding DLV-, IDV-, and NFV-related drug interactions.
2 Certain listed drugs are contraindicated based on theoretical considerations. Thus, drugs with narrow therapeutic indices and suspected metabolic involvement with CYP450 3A, 2D6, or unknown pathways are included in this table. Actual interactions may or may not occur in patients.
3 HIV-infected patients treated with rifapentine have a higher rate of TB relapse than those treated with other rifamycin-based regimens; an alternative agent is recommended.
4 A high rate of Grade 4 serum transaminase elevation was seen when a higher dose of RTV was added to LPV/r or SQV or when double-dose LPV/r was used with rifampin to compensate for rifampin's induction effect, so these dosing strategies should not be used.
5 The manufacturer of cisapride has a limited-access protocol for patients who meet specific clinical eligibility criteria.
6 Use of oral midazolam is contraindicated. Parenteral midazolam can be used with caution as a single dose and can be given in a monitored situation for procedural sedation.

Suggested alternatives to:
Lovastatin, simvastatin: Pravastatin and fluvastatin have the least potential for drug-drug interactions (except for pravastatin with DRV/r, see **Table 15a**). Use atorvastatin and rosuvastatin with caution; start with the lowest possible dose and titrate based on tolerance and lipid-lowering efficacy.
Rifampin: Rifabutin (with dosage adjustment – see **Tables 15a and 15b**)
Midazolam, triazolam: temazepam, lorazepam, oxazepam

Acronyms: ATV +/- RTV = atazanavir +/- ritonavir, DLV = delavirdine, DRV/r = darunavir/ritonavir, EFV = efavirenz, ETV = etravirine, FDA = Food and Drug Administration, FPV +/- RTV = fosamprenavir +/- ritonavir, HIV = human immunodeficiency virus, IDV = indinavir, LPV/r = lopinavir/ritonavir, MVC = maraviroc, NFV = nelfinavir, NNRTI = non-nucleoside reverse transcriptase inhibitor, NVP = nevirapine, PAH = pulmonary arterial hypertension, PI = protease inhibitor, RTV = ritonavir, SQV/r = saquinavir/ritonavir, TPV/r = tipranavir/ritonavir

Table 15a. Drug Interactions between PIs* and Other Drugs (Updated January 10, 2011)

*NFV and IDV are not included in this table. Please refer to the FDA package insert for information regarding NFV and IDV drug interactions.

This table provides information relating to pharmacokinetic interactions between PIs and non-ARV drugs. When information is available, interactions with boosted and unboosted PIs are listed separately. For interactions among ARV agents and for dosing recommendations, refer to **Table 16a**.

Concomitant Drug	PI	Effect on PI or Concomitant Drug Concentrations	Dosing Recommendations and Clinical Comments
Acid Reducers			
Antacids	ATV +/– RTV	↓ ATV expected when given simultaneously	Give ATV at least 2 hours before or 1 hour after antacids or buffered medications.
	FPV	APV AUC ↓ 18%; no significant change in APV C_{min}	Give FPV simultaneously with or at least 2 hours before or 1 hour after antacids.
	TPV/r	TPV AUC ↓ 27%	Give TPV at least 2 hours before or 1 hour after antacids.
H_2 receptor antagonists	**RTV-boosted PIs**		
	ATV/r	↓ ATV	H_2 receptor antagonist dose should not exceed a dose equivalent to famotidine 40 mg BID in ART-naïve patients or 20 mg BID in ART-experienced patients. Give ATV 300 mg + RTV 100 mg simultaneously with and/or ≥10 hours after the H_2 receptor antagonist. If using TDF and H_2 receptor antagonist in ART-experienced patients, use ATV 400 mg + RTV 100 mg.
	DRV/r, LPV/r	No significant effect	
	PIs without RTV		
	ATV	↓ ATV	H_2 receptor antagonist single dose should not exceed a dose equivalent of famotidine 20 mg or total daily dose equivalent of famotidine 20 mg BID in ART-naïve patients. Give ATV at least 2 hours before and at least 10 hours after the H_2 receptor antagonist.
	FPV	APV AUC ↓ 30%; no significant change in APV C_{min}	Give FPV at least 2 hours before H_2 receptor antagonist if concomitant use is necessary. Consider boosting with RTV.
Proton pump inhibitors (PPIs)	ATV	↓ ATV	**PPIs are not recommended in patients receiving unboosted ATV.** In these patients, consider alternative acid-reducing agents, RTV boosting, or alternative PIs.
	ATV/r	↓ ATV	PPIs should not exceed a dose equivalent to omeprazole 20 mg daily in PI-naïve patients. PPIs should be administered at least 12 hours prior to ATV/r. **PPIs are not recommended in PI-experienced patients**.
	DRV/r, TPV/r	↓ omeprazole PI: no significant effect	May need to increase omeprazole dose with TPV/r.
	FPV +/– RTV, LPV/r	No significant effect	
	SQV/r	SQV AUC ↑ 82%	Monitor for SQV toxicities.
Anticoagulants			
Warfarin	ATV +/- RTV, DRV/r, FPV +/- RTV, LPV/r, SQV/r, TPV/r	↑ or ↓ warfarin possible DRV/r ↓ S-warfarin AUC 21%	Monitor INR closely when stopping or starting PI and adjust warfarin dose accordingly.

Table 15a. Drug Interactions between PIs and Other Drugs

Concomitant Drug	PI	Effect on PI or Concomitant Drug Concentrations	Dosing Recommendations and Clinical Comments
Anticonvulsants			
Carbamazepine	**RTV-boosted PIs**		
	ATV/r, FPV/r, LPV/r, SQV/r, TPV/r	↑ carbamazepine possible TPV/r ↑ carbamazepine AUC 26% May ↓ PI levels substantially	Consider alternative anticonvulsant or monitor levels of both drugs and assess virologic response. **Do not coadminister with LPV/r once daily.**
	DRV/r	carbamazepine AUC ↑ 45% DRV: no significant change	Monitor anticonvulsant level and adjust dose accordingly.
	PIs without RTV		
	ATV, FPV	May ↓ PI levels substantially	Monitor anticonvulsant level and virologic response. Consider alternative anticonvulsant; RTV boosting for ATV and FPV; and/or monitoring PI level.
Lamotrigine	LPV/r	lamotrigine AUC ↓ 50% LPV: no significant change	Titrate lamotrigine dose to effect. A similar interaction is possible with other RTV-boosted PIs.
Phenobarbital	All PIs	May ↓ PI levels substantially	Consider alternative anticonvulsant or monitor levels of both drugs and assess virologic response. **Do not coadminister with LPV/r once daily.**
Phenytoin	**RTV-boosted PIs**		
	ATV/r, DRV/r, SQV/r, TPV/r	↓ phenytoin possible ↓ PI possible	Consider alternative anticonvulsant or monitor levels of both drugs and assess virologic response.
	FPV/r	phenytoin AUC ↓ 22% APV AUC ↑ 20%	Monitor phenytoin level and adjust dose accordingly. No change in FPV/r dose recommended.
	LPV/r	phenytoin AUC ↓ 31% LPV/r AUC ↓ 33%	Consider alternative anticonvulsant or monitor levels of both drugs and assess virologic response. **Do not coadminister with LPV/r once daily.**
	PIs without RTV		
	ATV, FPV	May ↓ PI levels substantially	Consider alternative anticonvulsant; RTV boosting for ATV and FPV; and/or monitoring PI level. Monitor anticonvulsant level and virologic response.
Valproic acid (VPA)	LPV/r	↓VPA possible LPV AUC ↑ 75%	Monitor VPA levels and response. Monitor for LPV-related toxicities.
Antidepressants			
Bupropion	LPV/r	bupropion AUC ↓ 57%	Titrate bupropion dose based on clinical response.
	TPV/r	bupropion AUC ↓ 46%	
Paroxetine	DRV/r	paroxetine AUC ↓ 39%	Titrate paroxetine dose based on clinical response.
	FPV/r	paroxetine AUC ↓ 58%	
Sertraline	DRV/r	sertraline AUC ↓ 49%	Titrate sertraline dose based on clinical response.
Trazodone	ATV +/- RTV, DRV/r, FPV +/- RTV, LPV/r, TPV/r	RTV 200 mg BID (for 2 days) ↑ trazodone AUC 240%	Use lowest dose of trazodone and monitor for CNS and cardiovascular adverse effects.
	SQV/r	↑ trazodone expected	**Contraindicated. Do not coadminister.**
Tricyclic antidepressants (TCAs) (amitriptyline, desipramine, imipramine, nortriptyline)	All RTV-boosted PIs	↑ TCA expected	Use lowest possible TCA dose and titrate based on clinical assessment and/or drug levels.

Concomitant Drug	PI	Effect on PI or Concomitant Drug Concentrations	Dosing Recommendations and Clinical Comments
Antifungals			
Fluconazole	**RTV-boosted PIs**		
	ATV/r	No significant effect	
	SQV/r	No data with RTV boosting SQV (1,200mg TID) AUC ↑ 50%	
	TPV/r	TPV AUC ↑ 50%	Fluconazole >200 mg daily is not recommended. If high-dose fluconazole is indicated, consider alternative PI or another class of ARV drug.
Itraconazole	**RTV-boosted PIs**		
	ATV/r, DRV/r, FPV/r, TPV/r	↑ itraconazole possible ↑ PI possible	Consider monitoring itraconazole level to guide dosage adjustments. High doses (>200 mg/day) are not recommended unless dosing is guided by drug levels.
	LPV/r	↑ itraconazole	Consider not exceeding 200 mg itraconazole daily or monitor itraconazole level.
	SQV/r	Bidirectional interaction has been observed	Dose not established, but decreased itraconazole dosage may be warranted. Consider monitoring itraconazole level.
	PIs without RTV		
	ATV, FPV	↑ itraconazole possible ↑ PI possible	Consider monitoring itraconazole level to guide dosage adjustments.
Posaconazole	ATV/r	ATV AUC ↑ 146%	Monitor for adverse effects of ATV.
	ATV	ATV AUC ↑ 268%	Monitor for adverse effects of ATV.
Voriconazole	**RTV-boosted PIs**		
	ATV/r, DRV/r, FPV/r, LPV/r, SQV/r, TPV/r	RTV 400 mg BID ↓ voriconazole AUC 82% RTV 100 mg BID ↓ voriconazole AUC 39%	**Do not coadminister** voriconazole and RTV unless benefit outweighs risk. If administered, consider monitoring voriconazole level.
	PIs without RTV		
	ATV, FPV	↑ voriconazole possible ↑ PI possible	Monitor for toxicities.
Anti-mycobacterials			
Clarithromycin	ATV +/− RTV	clarithromycin AUC ↑ 94%	May cause QTc prolongation. Reduce clarithromycin dose by 50%. Consider alternative therapy.
	DRV/r, FPV/r, LPV/r, SQV/r, TPV/r	DRV/r ↑ clarithromycin AUC 57% FPV/r ↑ clarithromycin possible LPV/r ↑ clarithromycin expected RTV 500 mg BID ↑ clarithromycin 77% SQV unboosted ↑ clarithromycin 45% TPV/r ↑ clarithromycin 19% and ↓ active metabolite 97% clarithromycin ↑ unboosted SQV 177% clarithromycin ↑ TPV 66%	Monitor for clarithromycin-related toxicities. Reduce clarithromycin dose by 50% in patients with CrCl 30–60 mL/min. Reduce clarithromycin dose by 75% in patients with CrCl <30 mL/min.
	FPV	APV AUC ↑ 18%	No dose adjustment

Concomitant Drug	PI	Effect on PI or Concomitant Drug Concentrations	Dosing Recommendations and Clinical Comments
Rifabutin	**RTV-boosted PIs**		
	ATV +/– RTV	rifabutin (150 mg once daily) AUC ↑ 110% and metabolite AUC ↑ 2,101% compared with rifabutin 300 mg daily alone	Rifabutin 150 mg every other day or three times a week. Some experts recommend rifabutin 150 mg daily or 300 mg three times a week. Monitor for antimycobacterial activity. Therapeutic drug monitoring for rifabutin is recommended. Rifabutin 150 mg three times a week in combination with LPV/r has resulted in inadequate rifabutin levels and has led to acquired rifamycin resistance in patients with HIV-associated TB. Pharmacokinetic data reported in this table are results from healthy volunteer studies.
	DRV/r	rifabutin (150 mg every other day) and metabolite AUC ↑ 55% compared with rifabutin 300 mg once daily alone	
	FPV/r	rifabutin (150 mg every other day) and metabolite AUC ↑ 64% compared with rifabutin 300 mg once daily alone	
	LPV/r	rifabutin (150mg once daily) and metabolite AUC ↑ 473% compared with rifabutin 300 mg daily alone	
	SQV/r	↑ rifabutin with unboosted SQV	
	TPV/r	rifabutin (150 mg x 1 dose) and metabolite AUC ↑ 333%	
	PIs without RTV		
	FPV	↑ rifabutin AUC expected	Rifabutin 150 mg daily or 300 mg three times a week
Rifampin	All PIs	↓ PI >75% approximately	**Do not coadminister rifampin and PIs.** Additional RTV does not overcome this interaction and increases hepatotoxicity.
Benzodiazepines			
Alprazolam **Diazepam**	All PIs	↑ benzodiazepine possible RTV 200 mg BID for two days ↑ alprazolam half-life 222% and AUC 248%	Consider alternative benzodiazepines such as lorazepam, oxazepam, or temazepam.
Lorazepam **Oxazepam** **Temazepam**	All PIs	No data	Metabolism of these benzodiazepines via non-CYP450 pathways decreases interaction potential compared with other benzodiazepines.
Midazolam	All PIs	↑ midazolam expected SQV/r ↑ midazolam (oral) AUC 1,144% and C_{max} 327%	**Do not coadminister oral midazolam and PIs.** Parenteral midazolam can be used with caution as a single dose and can be given in a monitored situation for procedural sedation.
Triazolam	All PIs	↑ triazolam expected RTV 200 mg BID ↑ triazolam half-life 1,200% and AUC 2,000%	**Do not coadminister triazolam and PIs.**
Cardiac Medications			
Bosentan	All PIs	LPV/r ↑ bosentan 48-fold (Day 4) and 5-fold (Day 10) ↓ ATV expected	**Do not coadminister bosentan and ATV without RTV.** In patients on a PI (other than unboosted ATV) >10 days: start bosentan at 62.5 mg once daily or every other day. In patients on bosentan who require a PI (other than unboosted ATV): stop bosentan ≥36 hours prior to PI initiation and restart 10 days after PI initiation at 62.5 mg once daily or every other day.

Concomitant Drug	PI	Effect on PI or Concomitant Drug Concentrations	Dosing Recommendations and Clinical Comments
Digoxin	RTV, SQV/r	RTV 200 mg BID ↑ digoxin AUC 29% and half-life 43% SQV/r ↑ digoxin AUC 49%	Use with caution. Monitor digoxin levels. Digoxin dose may need to be decreased.
Dihydropyridine calcium channel blockers (CCBs)	All PIs	↑ dihydropyridine possible	Use with caution. Titrate CCB dose and monitor closely. ECG monitoring is recommended when used with ATV.
Diltiazem	ATV +/– RTV	diltiazem AUC ↑ 125%	Decrease diltiazem dose by 50%. ECG monitoring is recommended.
	DRV/r, FPV +/– RTV, LPV/r, SQV/r, TPV/r	↑ diltiazem possible	Use with caution. Adjust diltiazem according to clinical response and toxicities.
Corticosteroids			
Dexamethasone	All PIs	↓ PI levels possible	Use systemic dexamethasone with caution or consider alternative corticosteroid for long-term use.
Fluticasone (inhaled or intranasal)	All RTV-boosted PIs	RTV 100 mg BID ↑ fluticasone AUC 350-fold and ↑ C_{max} 25-fold	Coadministration can result in adrenal insufficiency, including Cushing's syndrome. **Do not coadminister unless potential benefit outweighs risk of systemic corticosteroid adverse effects.**
Prednisone	LPV/r	↑ prednisolone AUC 31%	No dosage adjustment necessary.
Herbal Products			
St. John's wort	All PIs	↓ PI expected	**Do not coadminister.**
Hormonal Contraceptives			
Hormonal contraceptives	**RTV-boosted PIs**		
	ATV/r	↓ ethinyl estradiol ↑ norgestimate	Oral contraceptive should contain at least 35 mcg of ethinyl estradiol. Oral contraceptives containing progestins other than norethindrone or norgestimate have not been studied.
	DRV/r	ethinyl estradiol AUC ↓ 44% norethindrone AUC ↓ 14%	Use alternative or additional method.
	FPV/r	ethinyl estradiol AUC ↓ 37% norethindrone AUC ↓ 34%	Use alternative or additional method.
	LPV/r	ethinyl estradiol AUC↓ 42% norethindrone AUC ↓ 17%	Use alternative or additional method.
	SQV/r	↓ ethinyl estradiol	Use alternative or additional method.
	TPV/r	ethinyl estradiol AUC ↓ 48% norethindrone: no significant change	Use alternative or additional method.
	PIs without RTV		
	ATV	ethinyl estradiol AUC ↑ 48% norethindrone AUC ↑ 110%	Oral contraceptive should contain no more than 30 mcg of ethinyl estradiol or use alternate method. Oral contraceptives containing less than 25 mcg of ethinyl estradiol or progestins other than norethindrone or norgestimate have not been studied.
	FPV	With APV: ↑ ethinyl estradiol and ↑ norethindrone; ↓ APV 20%	Use alternative method.

Concomitant Drug	PI	Effect on PI or Concomitant Drug Concentrations	Dosing Recommendations and Clinical Comments
HMG-CoA Reductase Inhibitors			
Atorvastatin	All PIs	DRV/r + atorvastatin 10 mg similar to atorvastatin 40 mg alone; FPV +/– RTV ↑ atorvastatin AUC 130%–153%; LPV/r ↑ atorvastatin AUC 488%; SQV/r ↑ atorvastatin AUC 79%; TPV/r ↑ atorvastatin AUC 836%	Use lowest possible starting dose with careful monitoring for toxicities or consider other HMG-CoA reductase inhibitors with less potential for interaction.
Lovastatin	All PIs	Significant ↑ lovastatin expected	**Contraindicated. Do not coadminister.**
Pitavastatin	ATV	pitavastatin AUC ↑ 31%; C_{max} ↑ 60% ATV: no significant effect	No dosage adjustment needed for ATV without RTV.
	All RTV-boosted PIs	↑ pitavastatin possible	**Do not coadminister** due to possible increase in pitavastatin concentration and increased risk of rhabdomyolitis.
Pravastatin	DRV/r	pravastatin AUC ↑ 81%	Use lowest possible starting dose with careful monitoring.
	LPV/r	pravastatin AUC ↑ 33%	No dose adjustment necessary
	SQV/r	pravastatin AUC ↓ 47%–50%	No dose adjustment necessary
Rosuvastatin	ATV/r	rosuvastatin AUC ↑ 213% and C_{max} ↑ 600%	Use lowest possible starting dose with careful monitoring or consider other HMG-CoA reductase inhibitors with less potential for interaction.
	DRV/r, FPV +/- RTV, SQV/r	↑ rosuvastatin possible	
	LPV/r	rosuvastatin AUC ↑ 108% and C_{max} ↑ 366%	
	TPV/r	rosuvastatin AUC ↑ 26% and C_{max} ↑ 123%	
Simvastatin	All PIs	Significant ↑ simvastatin level; SQV/r 400 mg/400 mg BID ↑ simvastatin AUC 3,059%	**Contraindicated. Do not coadminister**.
Narcotics/Treatment for Opioid Dependence			
Buprenorphine	ATV	buprenorphine AUC ↑ 93% norbuprenorphine AUC ↑ 76% ↓ ATV possible	**Do not coadminister buprenorphine with unboosted ATV.** Norbuprenorphine is an active metabolite of buprenorphine.
	ATV/r	buprenorphine AUC ↑ 66% norbuprenorphine AUC ↑ 105%	Monitor for sedation. Buprenorphine dose reduction may be necessary. Norbuprenorphine is an active metabolite of buprenorphine.
	DRV/r	buprenorphine: no significant effect norbuprenorphine AUC ↑ 46% and C_{min} ↑ 71%	No dose adjustment necessary. Clinical monitoring is recommended. Norbuprenorphine is an active metabolite of buprenorphine.
	LPV/r	No significant effect	No dose adjustment necessary
	TPV/r	buprenorphine: no significant effect norbuprenorphine AUC, C_{max}, and C_{min} ↓ 80% TPV C_{min} ↓ 19–40%	Consider monitoring TPV level. Norbuprenorphine is an active metabolite of buprenorphine.
Methadone	**RTV-boosted PIs**		
	ATV/r, DRV/r, FPV/r, LPV/r, SQV/r, TPV/r	ATV/r, DRV/r, FPV/r ↓ R-methadone AUC 16%–18%; LPV/r ↓ methadone AUC 26%–53%; SQV/r 1,000/100mg BID ↓ R-methadone AUC 19%; TPV/r ↓ R-methadone AUC 48%	Opioid withdrawal unlikely but may occur. No adjustment in methadone usually required but monitor for opioid withdrawal and increase methadone dose as clinically indicated. (R-methadone is the active form of methadone.)

Table 15a. Drug Interactions between PIs and Other Drugs

Concomitant Drug	PI	Effect on PI or Concomitant Drug Concentrations	Dosing Recommendations and Clinical Comments
Methadone (continued)	**PIs without RTV**		
	ATV	No significant effect	No dosage adjustment necessary.
	FPV	No data with unboosted FPV APV ↓ R-methadone C_{min} 21%, AUC no significant change	Monitor and titrate methadone as clinically indicated. The interaction with FPV is presumed to be similar. (R-methadone is the active form of methadone.)
Phosphodiesterase Type 5 (PDE5) Inhibitors			
Sildenafil	All PIs	DRV/r + sildenafil 25mg similar to sildenafil 100mg alone; RTV 500 mg BID ↑ sildenafil AUC 1,000%; SQV unboosted ↑ sildenafil AUC 210%	For treatment of erectile dysfunction Start with sildenafil 25 mg every 48 hours and monitor for adverse effects of sildenafil. For treatment of pulmonary arterial hypertension **Contraindicated**
Tadalafil	All PIs	RTV 200 mg BID ↑ tadalafil AUC 124%; TPV/r (1st dose) ↑ tadalafil AUC 133%; TPV/r steady state: no significant effect	For treatment of erectile dysfunction Start with tadalafil 5 mg dose and do not exceed a single dose of 10 mg every 72 hours. Monitor for adverse effects of tadalafil. For treatment of pulmonary arterial hypertension *In patients on a PI >7 days*: Start with tadalafil 20 mg once daily and increase to 40 mg once daily based on tolerability. *In patients on tadalafil who require a PI*: Stop tadalafil ≥24 hours prior to PI initiation, restart 7 days after PI initiation at 20 mg once daily, and increase to 40 mg once daily based on tolerability.
Vardenafil	All PIs	RTV 600 mg BID ↑ vardenafil AUC 49-fold	Start with vardenafil 2.5 mg every 72 hours and monitor for adverse effects of vardenafil.
Miscellaneous Interactions			
All PIs	Colchicine	All PIs	For treatment of gout flares Colchicine 0.6 mg x 1 dose, followed by 0.3 mg 1 hour later. Do not repeat dose for at least 3 days. *With FPV without RTV*: 1.2 mg x 1 dose and no repeat dose for at least 3 days For prophylaxis of gout flares Colchicine 0.3 mg once daily or every other day *With FPV without RTV*: colchicine 0.3 mg BID or 0.6 mg once daily or 0.3 mg once daily For treatment of familial Mediterranean fever Do not exceed colchicine 0.6 mg once daily or 0.3 mg BID. *With FPV without RTV*: Do not exceed 1.2 mg once daily or 0.6 mg BID. **Do not coadminister in patients with hepatic or renal impairment.**
	Salmeterol	↑ salmeterol possible	**Do not coadminister** because of potential increased risk of salmeterol-associated cardiovascular events, including QT prolongation, palpitations, and sinus tachycardia.
ATV/r LPV/r	Atovaquone/proguanil	ATV/r ↓ atovaquone AUC 46% and ↓ proguanil AUC 41% LPV/r ↓ atovaquone AUC 74% and ↓ proguanil AUC 38%	No dosage recommendation. Consider alternative drug for malaria prophylaxis, if possible.

Acronyms: APV = amprenavir, ARV = antiretroviral, ATV = atazanavir, ATV/r = atazanavir + ritonavir, AUC = area under the curve, BID = twice daily, CCB = calcium channel blocker, C_{max} = maximum plasma concentration, C_{min} = minimum plasma concentration, CNS = central nervous system, CrCl = creatinine clearance, CYP = cytochrome P, DRV/r = darunavir + ritonavir, ECG = electrocardiogram, FDA = Food and Drug Administration, FPV = fosamprenavir (FPV is a prodrug of APV), FPV/r = fosamprenavir + ritonavir, IDV = indinavir, IDV/r = indinavir + ritonavir, INR = international normalized ratio, LPV = lopinavir, LPV/r = lopinavir + ritonavir, NFV = nelfinavir, PDE5 = phosphodiesterase type 5, PI = protease inhibitor, PPI = proton pump inhibitor, RTV = ritonavir, SQV = saquinavir, SQV/r = saquinavir + ritonavir, TB = tuberculosis, TCA = tricyclic antidepressant, TID = three times a day, TPV = tipranavir, TPV/r = tipranavir + ritonavir, VPA = valproic acid.

Table 15b. Drug Interactions between NNRTIs* and Other Drugs (Updated January 10, 2011)

*DLV is not included in this table. Please refer to the FDA package insert for information regarding DLV drug interactions.

This table provides information relating to pharmacokinetic interactions between NNRTIs and non-ARV drugs. For interactions among ARV agents and for dosing recommendations, refer to **Table 16b**.

Concomitant Drug Class/Name	NNRTI	Effect on NNRTI or Concomitant Drug Concentrations	Dosing Recommendations and Clinical Comments
Anticoagulants/Antiplatelets			
Warfarin	EFV, NVP	↑ or ↓ warfarin possible	Monitor INR and adjust warfarin dose accordingly.
	ETR	↑ warfarin possible	Monitor INR and adjust warfarin dose accordingly.
Clopidogrel	ETR	↓ activation of clopidogrel possible	ETR may prevent metabolism of clopidogrel (inactive) to its active metabolite. Avoid coadministration, if possible.
Anticonvulsants			
Carbamazepine **Phenobarbital** **Phenytoin**	EFV	carbamazepine + EFV: carbamazepine AUC ↓ 27% and EFV AUC ↓ 36% phenytoin + EFV: ↓ EFV and ↓ phenytoin possible	Monitor anticonvulsant and EFV levels or, if possible, use alternative anticonvulsant.
	ETR	↓ anticonvulsant and ETR possible	**Do not coadminister.** Consider alternative anticonvulsants.
	NVP	↓ anticonvulsant and NVP possible	Monitor anticonvulsant and NVP levels and virologic responses.
Antidepressants			
Bupropion	EFV	bupropion AUC ↓ 55%	Titrate bupropion dose based on clinical response.
Paroxetine	ETR	No significant effect	No dosage adjustment necessary.
Sertraline	EFV	sertraline AUC ↓ 39%	Titrate sertraline dose based on clinical response.
Antifungals			
Fluconazole	EFV	No significant effect	
	ETR	ETR AUC ↑ 86%	No dosage adjustment. Use with caution.
	NVP	NVP AUC ↑ 110%	Increased risk of hepatotoxicity possible with this combination Monitor NVP toxicity or use alternative antiretroviral agent.
Itraconazole	EFV	itraconazole and OH-itraconazole AUC, C_{max}, and C_{min} ↓ 35%–44%	Dose adjustments for itraconazole may be necessary. Monitor itraconazole level and antifungal response.
	ETR	↓ itraconazole possible ↑ ETR possible	Dose adjustments for itraconazole may be necessary. Monitor itraconazole level and antifungal response.
	NVP	↓ itraconazole possible ↑ NVP possible	Consider monitoring NNRTI and itraconazole levels and antifungal response.
Posaconazole	EFV	posaconazole AUC ↓ 50% ↔ EFV	Consider alternative antifungal if possible or consider monitoring posaconazole level if available.
	ETR	↑ ETR possible	No dosage adjustment necessary
Voriconazole	EFV	voriconazole AUC ↓ 77% EFV AUC ↑ 44%	**Contraindicated at standard doses**. Dose: voriconazole 400 mg BID, EFV 300 mg daily
	ETR	voriconazole AUC ↑ 14% ETR AUC ↑ 36%	No dosage adjustment; use with caution. Consider monitoring voriconazole level.
	NVP	↓ voriconazole possible ↑ NVP possible	Monitor for toxicity and antifungal response and/or voriconazole level.
Antimycobacterials			
Clarithromycin	EFV	clarithromycin AUC ↓ 39%	Monitor for efficacy or consider alternative agent, such as azithromycin, for MAC prophylaxis and treatment.
	ETR	clarithromycin AUC ↓ 39% OH-clarithromycin AUC ↑ 21% ETR AUC ↑ 42%	Consider alternative agent, such as azithromycin, for MAC prophylaxis and treatment.
	NVP	clarithromycin AUC ↓ 31% OH-clarithromycin AUC ↑ 42%	Monitor for efficacy or use alternative agent, such as azithromycin, for MAC prophylaxis and treatment.

Table 15b. Drug Interactions between NNRTIs* and Other Drugs
Page 2 of 3

Concomitant Drug Class/Name	NNRTI	Effect on NNRTI or Concomitant Drug Concentrations	Dosing Recommendations and Clinical Comments
Antimycobacterials (continued)			
Rifabutin	EFV	rifabutin ↓ 38%	Dose: rifabutin 450–600 mg once daily or 600 mg three times a week if EFV is not coadministered with a PI.
	ETR	rifabutin and metabolite AUC ↓ 17% ETR AUC ↓ 37%	**If ETR is used with an RTV-boosted PI, rifabutin should not be coadministered.** Dose: rifabutin 300 mg once daily **if** ETR is not coadministered with an RTV-boosted PI.
	NVP	rifabutin AUC ↑ 17% and metabolite AUC ↑ 24% NVP C_{min} ↓ 16%	No dosage adjustment necessary. Use with caution.
Rifampin	EFV	EFV AUC ↓ 26%	Maintain EFV dose at 600 mg once daily and monitor for virologic response. Some clinicians suggest EFV 800 mg dose in patients >60kg.
	ETR	Significant ↓ ETR possible	**Do not coadminister.**
	NVP	NVP ↓ 20%–58%	**Do not coadminister.**
Benzodiazepines			
Alprazolam	EFV, ETR, NVP	No data	Monitor for therapeutic efficacy of alprazolam.
Diazepam	ETR	↑ diazepam possible	Decreased dose of diazepam may be necessary.
Lorazepam	EFV	lorazepam C_{max} ↑ 16%, AUC no significant effect	No dosage adjustment necessary
Midazolam	EFV	Significant↑ midazolam expected	**Do not coadminister with oral midazolam.** Parenteral midazolam can be used with caution as a single dose and can be given in a monitored situation for procedural sedation.
Triazolam	EFV	Significant ↑ triazolam expected	**Do not coadminister.**
Cardiac Medications			
Dihydropyridine calcium channel blockers (CCBs)	EFV, NVP	↓ CCBs possible	Titrate CCB dose based on clinical response.
Diltiazem	EFV	diltiazem AUC ↓ 69%	Titrate diltiazem dose based on clinical response.
	NVP	↓ diltiazem possible	
Corticosteroids			
Dexamethasone	ETR*	↓ ETR possible	Use systemic dexamethasone with caution or consider alternative corticosteroid for long-term use.
Herbal Products			
St. John's wort	EFV, ETR, NVP	↓ NNRTI	**Do not coadminister.**
Hormonal Contraceptives			
Hormonal contraceptives	EFV	ethinyl estradiol ↔ levonorgestrel AUC ↓ 83% norelgestromin AUC ↓ 64%	Use alternative or additional methods. Norelgestromin and levonorgestrel are active metabolites of norgestimate.
	ETR	ethinyl estradiol AUC ↑ 22% norethindrone: no significant effect	No dosage adjustment necessary.
	NVP	ethinyl estradiol AUC ↓ 20% norethindrone AUC ↓ 19%	Use alternative or additional methods.
		depomedroxyprogesterone acetate: no significant change	No dosage adjustment necessary
Levonorgestrel	EFV	levonorgestrel AUC ↓ 58%	Effectiveness of emergency postcoital contraception may be diminished.
HMG-CoA Reductase Inhibitors			
Atorvastatin	EFV, ETR, NVP	atorvastatin AUC ↓ 32%–43% with EFV, ETR	Adjust atorvastatin according to lipid responses, not to exceed the maximum recommended dose.
Fluvastatin	ETR	↑ fluvastatin possible	Dose adjustments for fluvastatin may be necessary.

** Error corrected January 18, 2011*

Table 15b. Drug Interactions between NNRTIs* and Other Drugs
Page 3 of 3

Concomitant Drug Class/Name	NNRTI	Effect on NNRTI or Concomitant Drug Concentrations	Dosing Recommendations and Clinical Comments
HMG-CoA Reductase Inhibitors (continued)			
Lovastatin **Simvastatin**	EFV	simvastatin AUC ↓ 68%	Adjust simvastatin dose according to lipid responses, not to exceed the maximum recommended dose. If used with RTV-boosted PI, simvastatin and lovastatin should be avoided.
	ETR, NVP	↓ lovastatin possible ↓ simvastatin possible	Adjust lovastatin or simvastatin dose according to lipid responses, not to exceed the maximum recommended dose. If used with RTV-boosted PI, simvastatin and lovastatin should be avoided.
Pitavastatin	EFV, ETR, NVP	No data	No dosage recommendation
Pravastatin **Rosuvastatin**	EFV	pravastatin AUC ↓ 44% rosuvatatin: no data	Adjust statin dose according to lipid responses, not to exceed the maximum recommended dose.
	ETR	No significant effect expected with either pravastatin or rosuvastatin	No dosage adjustment necessary
Narcotics/Treatment for Opioid Dependence			
Buprenorphine	EFV	buprenorphine AUC ↓ 50% norbuprenorphine AUC ↓ 71%	No withdrawal symptoms reported. No dosage adjustment recommended, but monitor for withdrawal symptoms.
	NVP	No significant effect	No dosage adjustment necessary
Methadone	EFV	methadone AUC ↓ 52%	Opioid withdrawal common; increased methadone dose often necessary.
	ETR	No significant effect	No dosage adjustment necessary
	NVP	methadone AUC ↓ 41% NVP: no significant effect	Opioid withdrawal common; increased methadone dose often necessary.
Phosphodiesterase Type 5 (PDE5) Inhibitors			
Sildenafil	ETR	sildenafil AUC ↓ 57%	May need to increase sildenafil dose based on clinical effect.
Tadalafil	ETR	↓ tadalafil possible	May need to increase tadalafil dose based on clinical effect.
Vardenafil	ETR	↓ vardenafil possible	May need to increase vardenafil dose based on clinical effect.
Miscellaneous Interactions			
Atovaquone/proguanil	EFV	↓ atovaquone AUC 75% ↓ progaunil AUC 43%	No dosage recommendation. Consider alternative drug for malaria prophylaxis, if possible.

Acronyms: ARV = antiretroviral, AUC = area under the curve, CCB = calcium channel blocker, C_{max} = maximum plasma concentration, C_{min} = minimum plasma concentration, DLV = delavirdine, EFV = efavirenz, ETR = etravirine, FDA = Food and Drug Administration, INR = international normalized ratio, MAC = *Mycobacterium avium* complex, NNRTI = non-nucleoside reverse transcriptase inhibitor, NVP = nevirapine, OH-clarithromycin = active metabolite of clarithromycin, PDE5 = phosphodiesterase type 5, PI = protease inhibitor

Table 15c. Drug Interactions between NRTIs and Other Drugs (Including ARV Agents)
(Updated January 10, 2011)

Concomitant Drug Class/Name	NRTI	Effect on NRTI or Concomitant Drug Concentrations	Dosage Recommendations and Clinical Comments
Antivirals			
Ganciclovir Valganciclovir	TDF	No data	Serum concentrations of these drugs and/or TDF may be increased. Monitor for dose-related toxicities.
	ZDV	No significant pharmacokinetic effects	Potential increase in hematologic toxicities
Ribavirin	ddI	↑ intracellular ddI	**Contraindicated. Do not coadminister.** Fatal hepatic failure and other ddI-related toxicities have been reported with coadministration.
	ZDV	Ribavirin inhibits phosphorylation of ZDV.	Avoid coadministration if possible or closely monitor virologic response and hematologic toxicities.
Integrase Inhibitor			
RAL	TDF	RAL AUC ↑ 49%, C_{max} ↑ 64%	No dosage adjustment necessary
Narcotics/Treatment for Opioid Dependence			
Buprenorphine	3TC, ddI, TDF, ZDV	No significant effect	No dosage adjustment necessary
Methadone	ABC	methadone clearance ↑ 22%	No dosage adjustment necessary
	d4T	d4T AUC ↓ 23% and C_{max} ↓ 44%	No dosage adjustment necessary
	ZDV	ZDV AUC ↑ 29%–43%	Monitor for ZDV-related adverse effects.
NRTIs			
ddI	d4T	No significant PK interaction	**Avoid coadministration**. Additive toxicities of peripheral neuropathy, lactic acidosis, and pancreatitis seen with this combination.
	TDF	ddI-EC AUC and C_{max} ↑ 48%–60%	**Avoid coadministration**.
Other			
Allopurinol	ddI	ddI AUC ↑ 113% ddI AUC ↑ 312% with renal impairment	**Contraindicated. Do not coadminister.** Potential for increased ddI-associated toxicities.
PIs			
ATV	ddI	With ddI-EC + ATV (with food): ddI AUC ↓ 34%; ATV no change	Administer ATV with food 2 hours before or 1 hour after didanosine.
	TDF	ATV AUC↓ 25% and C_{min} ↓ 23%–40% (higher C_{min} with RTV than without) TDF AUC ↑ 24%–37%	Dose: ATV/r 300/100 mg daily coadministered with TDF 300 mg daily. Avoid concomitant use without RTV. If using TDF and H_2 receptor antagonist in ART-experienced patients, use ATV/r 400 mg/100 mg daily. Monitor for TDF-associated toxicity.
	ZDV	ZDV C_{min} ↓ 30%, no change in AUC	Clinical significance unknown.
DRV/r	TDF	TDF AUC↑ 22%, C_{max} ↑ 24% and C_{min} ↑ 37%	Clinical significance unknown. Monitor for TDF toxicity.
LPV/r	TDF	LPV/r AUC ↓ 15% TDF AUC ↑ 34%	Clinical significance unknown. Monitor for TDF toxicity.
TPV/r	ABC	ABC ↓ 35%–44% with TPV/r 1,250/100 mg BID	Appropriate doses for this combination have not been established.
	ddI	ddI-EC ↓ 10% and TPV C_{min} ↓34% with TPV/r 1,250/100 mg BID	Separate doses by at least 2 hours.
	ZDV	ZDV AUC ↓ 31%–43% and C_{max} ↓ 46%–51% with TPV/r 1,250/100 mg BID	Appropriate doses for this combination have not been established.

Acronyms: 3TC = lamivudine, ABC = abacavir, ARV = antiretroviral, ATV = atazanavir, AUC = area under the curve, BID = twice daily, C_{max} = maximum plasma concentration, C_{min} = minimum plasma concentration, d4T = stavudine, ddI = didanosine, DRV/r = darunavir/ritonavir, EC = enteric coated, LPV/r = lopinavir/ritonavir, NRTI = nucleoside reverse transcriptase inhibitor, PI = protease inhibitor, PK = pharmacokinetic, RAL = raltegravir, TDF = tenofovir, TPV/r = tipranavir/ritonavir, ZDV = zidovudine.

Table 15d. Drug Interactions between CCR5 Antagonist and Other Drugs (Updated January 10, 2011)

This table provides information relating to pharmacokinetic interactions between MVC and non-ARV drugs. For interactions among ARV agents and for dosing recommendations, please refer to **Table 16b**.

Concomitant Drug Class/Name	CCR5 Antagonist	Effect on CCR5 Antagonist or Concomitant Drug Concentrations	Dosing Recommendations and Clinical Comments
Anticonvulsants			
Carbamazepine Phenobarbital Phenytoin	MVC	↓ MVC possible	If used without a strong CYP3A inhibitor, use MVC 600 mg BID or an alternative antiepileptic agent.
Antifungal			
Itraconazole	MVC	↑ MVC possible	Dose: MVC 150 mg BID
Ketoconazole	MVC	MVC AUC ↑ 400%	Dose: MVC 150 mg BID
Voriconazole	MVC	↑ MVC possible	Consider dose reduction to MVC 150 mg BID
Antimycobacterials			
Clarithromycin	MVC	↑ MVC possible	Dose: MVC 150 mg BID
Rifabutin	MVC	↓ MVC possible	If used without a strong CYP3A inducer or inhibitor, use MVC 300 mg BID. If used with a strong CYP3A inhibitor, use MVC 150 mg BID.
Rifampin	MVC	MVC AUC ↓ 64%	Coadministration is not recommended. If coadministration is necessary use MVC 600 mg BID. If coadministered with a strong CYP3A inhibitor, use MVC 300 mg BID.
Herbal Products			
St. John's wort	MVC	↓ MVC possible	Coadministration is not recommended.
Hormonal Contraceptives			
Hormonal contraceptives	MVC	No significant effect on ethinyl estradiol or levonorgestrel	Safe to use in combination
Narcotics/Treatment for Opioid Dependence			
Methadone	MVC	No data	

Acronyms: ARV = antiretroviral, AUC = area under the curve, BID = twice daily, CYP = cytochrome P, MVC = maraviroc

Table 15e. Drug Interactions between Integrase Inhibitor and Other Drugs (Updated January 10, 2011)

Concomitant Drug Class/Name	Integrase Inhibitor	Effect on Integrase Inhibitor or Concomitant Drug Concentrations	Dosing Recommendations and Clinical Comments
Acid Reducers			
Omeprazole	RAL	RAL AUC ↑ 212%, C_{max} ↑ 315%, and C_{min} ↑ 46%	No dosage adjustment recommended
Antimycobacterials			
Rifabutin	RAL	RAL AUC ↑ 19%, C_{max} ↑ 39%, and C_{min} ↓ 20%	No dosage adjustment recommended
Rifampin	RAL	RAL AUC ↓ 40% and C_{min} ↓ 61% with RAL 400 mg Rifampin with RAL 800 mg BID compared with RAL 400 mg BID alone: RAL AUC ↑ 27% and C_{min} ↓ 53%	Dose: RAL 800 mg BID Monitor closely for virologic response.
Hormonal Contraceptives			
Hormonal contraceptives	RAL	No clinically significant effect	Safe to use in combination
Narcotics/Treatment for Opioid Dependence			
Methadone	RAL	No significant effect	No dosage adjustment necessary

Acronyms: AUC = area under the curve, BID = twice daily, C_{max} = maximum plasma concentration, C_{min} = minimum plasma concentration, RAL = raltegravir

Table 16a. Interactions Among PIs* (Updated January 10, 2011)

Preventing Secondary Transmission of HIV

(Updated December 1, 2009)

PREVENTION COUNSELING

Interventions to prevent transmission of HIV are key components of the management of HIV infection, yet multiple studies show that prevention is frequently neglected in clinical practice. Each patient encounter provides opportunities to reinforce HIV prevention messages—messages that patients often look to their providers to deliver but may fail to receive *[1-2]*. Despite the challenges to providing effective prevention interventions in a busy practice setting, multiple approaches are available, including formal guidance from the Centers for Disease Control and Prevention (CDC) for incorporating HIV prevention into medical care settings *[3]*. Such interventions have been demonstrated to be effective in changing sexual risk behavior *[4-6]*and can reinforce self-directed behavior change early in diagnosis *[7]*.

The CDC has identified prevention interventions for HIV-infected people that meet stringent criteria for efficacy and scientific rigor *[8]* and three that demonstrated efficacy in treatment settings (Options, Partnership for Health, and Positive Choices). The interventions are available through CDC trainings and materials, delivered as brief messages by providers or via laptop computer, and are readily implemented into busy clinics (**http://www.cdc.gov/hiv/topics/research/prs/index.htm**).

Evidence also exists regarding the efficacy of interventions to reduce injection drug use risk behavior. These include both behavioral interventions *[9-11]* and opiate substitution treatment with methadone *[12-13]*.

There is evidence of increases in HIV risk behaviors among infected persons coinciding with the availability of potent combination antiretroviral therapy (ART). In some cohorts the rate of reported risk behaviors almost doubled compared with rates in the era prior to such therapies *[7]*. A meta-analysis of studies of HIV risk behaviors demonstrates that the prevalence of unprotected sex acts increased in those who believed that receiving ART or having a suppressed viral load protects against transmitting HIV *[14]*. Attitudinal shifts away from safer sexual practices since the availability of potent ART underscore the role for provider-initiated HIV prevention counseling. With wider recognition of the concept that effective treatment may decrease the probability of transmission, it is particularly important for providers to help patients understand that a sustained viral load below the limits of detection will dramatically reduce but does not absolutely assure the absence of virus in the genital and blood compartments, and hence the inability to transmit virus to others *[14-15]*.

Additionally, given the role of sexually transmitted infections (STIs) as facilitators of HIV transmission, an essential adjunct to prevention counseling is the routine screening and symptom-directed testing for STIs, as recommended by CDC *[3]*.

ANTIRETROVIRAL THERAPY AS PREVENTION

ART does have a role in preventing HIV transmission. Lower levels of plasma RNA have been associated with decreases in the concentration of virus in genital secretions *[16-17]*. Observational studies have demonstrated a decreased rate of HIV transmission among serodiscordant heterosexual couples following antiretroviral (ARV)-induced viral suppression in the absence of concomitant STIs. Multiple studies have demonstrated a direct correlation between HIV inoculum size (i.e., viral load) and probability of transmission *[18-19]*. Although some data suggest that the risk of heterosexual HIV transmission is low when an individual's viral load is <40 copies/mL, these data are contingent upon several assumptions, including: (1) completely suppressed viremia; (2) complete adherence to an effective ARV regimen; and (3) the absence of a concomitant STI. Detection of HIV RNA in the genital secretions has been documented in individuals with controlled plasma HIV RNA *[20-21]*. Moreover, it is critical that any biological reduction in infectivity not be offset by increases in risk behavior (i.e., risk compensation).

SUMMARY

In summary, consistent and effective use of ART resulting in a sustained reduction in viral load, in conjunction with consistent condom usage, safer sexual and drug use practices, and detection and treatment of STIs are essential tools for prevention of sexual and blood-borne transmission of HIV. Given these important considerations, medical visits provide a vital opportunity to reinforce HIV prevention messages, discuss sexual- and drug-related risk behaviors, diagnose and treat intercurrent STIs, and develop open communication between provider and patient.

Conclusion

The Panel has carefully reviewed recent results from clinical trials in HIV therapy and considered how they inform appropriate care guidelines. The Panel appreciates that HIV care is highly complex and rapidly evolving. Guidelines are never fixed and must always be individualized. Where possible, the Panel has based recommendations on the best evidence from prospective trials with defined endpoints. When such evidence does not yet exist, the Panel attempted to reflect reasonable options in its conclusions.

HIV care requires, as always, partnerships and open communication. The provider can make recommendations most likely to lead to positive outcomes only if the patient's own point of view and social context are well known. Guidelines are only a starting point for medical decision making. They can identify some of the boundaries of high-quality care but cannot substitute for sound judgment.

As further research is conducted and reported, guidelines will be modified. The Panel anticipates continued progress in the simplicity of regimens, improved potency and barrier to resistance, and reduced toxicity. The Panel hopes the guidelines are useful and is committed to their continued adjustment and improvement.

Appendix A: Key to Acronyms

3TC	lamivudine
3TC/ZDV	lamivudine + zidovudine
ABC	abacavir
ABC/3TC	abacavir + lamivudine
ABC/3TC/ZDV	abacavir + lamivudine + zidovudine
ACTG	AIDS Clinical Trials Group
AIDS	acquired immune deficiency syndrome
ALT	alanine aminotransferase
APV	amprenavir
ART	antiretroviral therapy
ART-CC	ART Cohort Collaboration
ARV	antiretroviral
AST	aspartate aminotransferase
ATV	atazanavir
ATV/r	atazanavir/ritonavir or ritonavir-boosted atazanavir
AUC	area under the curve
AV	atrioventricular
bDNA	branched DNA
BID	twice a day
BMD	bone mineral density
BUN	blood urea nitrogen
CAPD	chronic ambulatory peritoneal dialysis
CBC	complete blood count
CCB	calcium channel blocker
CDC	Centers for Disease Control and Prevention
CI	confidence interval
C_{max}	maximum concentration or peak concentration
CME	continuing medical education
C_{min}	minimum concentration or trough concentration
CMV	cytomegalovirus
CNS	central nervous system
CPK	creatine phosphokinase
CrCl	creatinine clearance
CVD	cardiovascular disease
CYP	cytochrome P
d4T	stavudine
D:A:D	Data Collection on Adverse Events of Anti-HIV Drugs Study
ddC	zalcitabine
ddI	didanosine
DHHS	Department of Health and Human Services
DILI	drug-induced liver injury
DLV	delavirdine
DM	diabetes mellitus
D/M	dual or mixed (tropic)
DMPA	depot medroxyprogesterone
DOT	directly observed therapy
DRV	darunavir
DRV/r	darunavir/ritonavir or ritonavir-boosted darunavir

DXA	dual-energy x-ray absorptiometry
EBV	Epstein-Barr virus
EC	enteric coated
ECG	electrocardiogram
EFV	efavirenz
EFV/FTC/TDF	efavirenz + emtricitabine + tenofovir disoproxil fumarate
EIA	enzyme immunoassay
ETR	etravirine
FDA	Food and Drug Administration
FI	fusion inhibitor
FPV	fosamprenavir
FPV/r	fosamprenavir/ritonavir or ritonavir-boosted fosamprenavir
FTC	emtricitabine
FTC/TDF	emtricitabine + tenofovir disoproxil fumarate
GAZT	AZT glucuronide
GHB	gamma hydroxybutyrate
GI	gastrointestinal
HAV	hepatitis A virus
HBeAg	hepatitis B e antigen
HBsAg	hepatitis B surface antigen
HBV	hepatitis B virus
HCV	hepatitis C virus
HD	hemodialysis
HDL	high-density lipoprotein
HELLP	hemolysis, elevated liver enzymes, low platelet count (syndrome)
HHS	Health and Human Services
HHV	human herpes virus
HHV-8	human herpes virus 8
HIV	human immunodeficiency virus
HIV-1	human immunodeficiency virus type 1
HIV-2	human immunodeficiency virus type 2
HIVAN	HIV-associated nephropathy
HPV	human papilloma virus
HR	hazard ratio
HRSA	Health Resource Services Administration
hsCRP	high sensitivity C-reactive protein
HSR	hypersensitivity reaction
HTLV	human T-cell leukemia virus
HTLV-1	human T-cell leukemia virus type 1
HTLV-2	human T-cell leukemia virus type 2
IAS-USA	International AIDS Society-USA
IC	inhibitory concentration
IDU	illicit drug user
IDV	indinavir
IDV/r	indinavir/ritonavir or ritonavir-boosted indinavir
IFN-γ	interferon-gamma
IGRA	interferon-gamma release assay
IL-2	interleukin-2
IL-6	interleukin-6
IL-7	interleukin-7
IND	investigational new drug

INH	isoniazid
INR	international normalized ratio
INSTI	integrase strand transfer inhibitor
IQ	inhibitory quotient
IRB	Institutional Review Board
IRIS	immune reconstitution inflammatory syndrome
LDL	low-density lipoprotein
LPV	lopinavir
LPV/r	lopinavir/ritonavir or ritonavir-boosted lopinavir
LTBI	latent tuberculosis infection
MAC	*Mycobacterium avium* complex
MDMA	methylenedioxymethamphetamine
MDRD	modification of diet in renal disease (equation)
MHC	major histocompatability complex
MI	myocardial infarction
msec	milliseconds
MSM	men who have sex with men
MTB	*Mycobacterium tuberculosis*
MTCT	mother-to-child transmission
MVC	maraviroc
NA-ACCORD	The North American AIDS Cohort Collaboration on Research and Design
NFV	nelfinavir
NIH	National Institutes of Health
NNRTI	non-nucleoside reverse transcriptase inhibitor
NRTI	nucleoside reverse transcriptase inhibitor
NVP	nevirapine
OAR	Office of AIDS Research
OARAC	Office of AIDS Research Advisory Council
PAH	pulmonary arterial hypertension
PCP	*Pneumocystis jirocevi* pneumonia
PDE5	phosphodiesterase type 5
PI	protease inhibitor
PK	pharmacokinetic
PMTCT	prevention of mother-to-child transmission
PO	by mouth
PPI	proton pump inhibitor
PR	protease (gene)
PT	prothrombin time
RAL	raltegravir
RT	reverse transcriptase (gene)
RT-PCR	reverse transcriptase-polymerase chain reaction
RTV	ritonavir
SJS	Stevens-Johnson syndrome
SPT	skin patch test
SQV	saquinavir
SQV/r	saquinavir/ritonavir or ritonavir-boosted saquinavir
STI	sexually transmitted infection
$t_{½}$	half-life

T-20	enfuvirtide
TAM	thymidine analogue mutation
TB	tuberculosis
TCA	tricyclic antidepressant
TDF	tenofovir disoproxil fumarate or tenofovir
TDM	therapeutic drug monitoring
TEN	toxic epidermal necrosis
TG	triglyceride
TID	three times a day
TPV	tipranavir
TPV/r	tipranavir/ritonavir or ritonavir-boosted tipranavir
TST	tuberculin skin test
UDP	uridine diphosphate
UGT1A1	uridine diphosphate glucuronosyltransferase 1A1
VPA	valproic acid
WBC	white blood cell
WHO	World Health Organization
WITS	Women and Infants Transmission Study
ZDV	zidovudine

Appendix B, Table 1. Characteristics of Nucleoside Reverse Transcriptase Inhibitors (NRTIs)

(Updated January 10, 2011)

Generic Name (abbreviation)/ Trade Name	Formulations	Dosing Recommendations (For dosage adjustment in renal or hepatic insufficiency, see Appendix B, Table 7.)	Elimination	Serum/ Intracellular Half-lives	Adverse Events (Also see Table 13)
Abacavir (ABC)/ Ziagen **Also available as**:	Ziagen - 300-mg tablets - 20-mg/mL oral solution	Ziagen 300 mg BID or 600 mg once daily Take without regard to meals	Metabolized by alcohol dehydrogenase and glucuronyl transferase Renal excretion of metabolites 82% Dosage adjustment for ABC recommended in patients with hepatic insufficiency (See **Appendix B, Table 7**.)	1.5 hrs/ 12–26 hrs	• *Hypersensitivity reactions (HSR)*: Patients positive for HLA-B*5701 are at highest risk. HLA screening should be done prior to initiation of ABC. Rechallenge is not recommended. • Symptoms of HSR may include fever, rash, nausea, vomiting, diarrhea, abdominal pain, malaise, or fatigue or respiratory symptoms such as sore throat, cough, or shortness of breath. • Some cohort studies suggest increased risk of myocardial infarction (MI) with recent or current use of ABC, but this risk is not substantiated in other studies.
Trizivir ABC with ZDV+3TC	Trizivir ABC 300 mg + ZDV 300 mg + 3TC 150 mg	Trizivir 1 tablet BID			
Epzicom ABC with 3TC	Epzicom ABC 600 mg + 3TC 300 mg	Epzicom 1 tablet once daily			
Didanosine (ddI)/ Videx EC (generic available; dose same as Videx EC)	Videx EC 125-, 200-, 250-, 400-mg capsules Buffered tablets (non-EC) no longer available Videx 10-mg/mL oral solution	**Body weight ≥60kg**: 400 mg once daily* *With TDF*: 250 mg once daily **Body weight <60kg**: 250 mg once daily* *With TDF*: 200 mg once daily Take 1/2 hour before or 2 hours after a meal *Preferred dosing with oral solution is BID (total daily dose divided into 2 doses)	Renal excretion 50% Dosage adjustment in renal insufficiency recommended (See **Appendix B, Table 7**.)	1.5 hrs/ >20 hrs	• Pancreatitis • Peripheral neuropathy • Retinal changes, optic neuritis • Lactic acidosis with hepatic steatosis +/- pancreatitis (rare but potentially life-threatening toxicity) • Nausea, vomiting • Potential association with noncirrhotic portal hypertension, some cases presented with esophageal varices • One cohort study suggested increased risk of MI with recent or current use of ddI, but this risk is not substantiated in other studies. • Insulin resistance/diabetes mellitus
Emtricitabine (FTC)/ Emtriva **Also available as:**	Emtriva - 200-mg hard gelatin capsule - 10-mg/mL oral solution	Emtriva *Capsule*: 200 mg once daily *Oral solution*: 240 mg (24 mL) once daily Take without regard to meals	Renal excretion 86% Dosage adjustment in renal insufficiency recommended (See **Appendix B, Table 7**.)	10 hrs/ >20 hrs	• Minimal toxicity • Hyperpigmentation/skin discoloration • Severe acute exacerbation of hepatitis may occur in HBV-coinfected patients who discontinue FTC.
Atripla FTC with EFV+TDF	Atripla FTC 200 mg + EFV 600 mg + TDF 300 mg	Atripla 1 tablet at or before bedtime Take on an empty stomach to reduce side effects			
Truvada FTC with TDF	Truvada FTC 200 mg + TDF 300 mg	Truvada 1 tablet once daily			

Appendix B, Table 1. Characteristics of Nucleoside Reverse Transcriptase Inhibitors (NRTIs)

Generic Name (abbreviation)/ Trade Name	Formulations	Dosing Recommendations (For dosage adjustment in renal or hepatic insufficiency, see Appendix B, Table 7.)	Elimination	Serum/ Intracellular Half-lives	Adverse Events (Also see Table 13)
Lamivudine (3TC)/ Epivir **Also available as:**	Epivir • 150-, 300-mg tablets • 10-mg/mL oral solution	Epivir 150 mg BID or 300 mg once daily Take without regard to meals	Renal excretion 70% Dosage adjustment in renal insufficiency recommended (See Appendix B, Table 7.)	5–7 hrs/ 18–22 hrs	• Minimal toxicity • Severe acute exacerbation of hepatitis may occur in HBV-coinfected patients who discontinue 3TC.
Combivir 3TC with ZDV	Combivir 3TC 150 mg + ZDV 300 mg	Combivir 1 tablet BID			
Epzicom 3TC with ABC	Epzicom 3TC 300 mg + ABC 600 mg	Epzicom 1 tablet once daily			
Trizivir 3TC with ZDV+ABC	Trizivir 3TC 150 mg + ZDV 300 mg + ABC 300 mg	Trizivir 1 tablet BID			
Stavudine (d4T)/ Zerit	Zerit • 15-, 20-, 30-, 40-mg capsules • 1-mg/mL oral solution	**Body weight ≥60 kg**: 40 mg BID **Body weight <60 kg**: 30 mg BID* Take without regard to meals *WHO recommends 30 mg BID dosing regardless of body weight.	Renal excretion 50% Dosage adjustment in renal insufficiency recommended (See Appendix B, Table 7.)	1 hr/ 7.5 hrs	• Peripheral neuropathy • Lipoatrophy • Pancreatitis • Lactic acidosis/severe hepatomegaly with hepatic steatosis (rare but potentially life-threatening toxicity) • Hyperlipidemia • Insulin resistance/diabetes mellitus • Rapidly progressive ascending neuromuscular weakness (rare)
Tenofovir Disoproxil Fumarate (TDF)/ Viread **Also available as:**	Viread 300-mg tablet	Viread 1 tablet once daily Take without regard to meals	Renal excretion Dosage adjustment in renal insufficiency recommended (See Appendix B, Table 7.)	17 hrs/ >60 hrs	• Renal insufficiency, Fanconi syndrome • Osteomalacia • Potential decrease in bone mineral density • Severe acute exacerbation of hepatitis may occur in HBV-coinfected patients who discontinue TDF. • Asthenia, headache, diarrhea, nausea, vomiting, and flatulence
Atripla TDF with EFV+FTC	Atripla TDF 300 mg + EFV 600 mg + FTC 200 mg	Atripla 1 tablet at or before bedtime Take on an empty stomach to reduce side effects			
Truvada TDF with FTC	Truvada TDF 300 mg + FTC 200 mg	Truvada 1 tablet once daily Take without regard to meals			
Zidovudine (ZDV)/ Retrovir (generic available; dose same as retrovir) **Also available as:**	Retrovir • 100-mg capsules • 300-mg tablets • 10-mg/mL intravenous solution • 10-mg/mL oral solution	Retrovir 300 mg BID or 200 mg TID Take without regard to meals	Metabolized to GAZT Renal excretion of GAZT Dosage adjustment in renal insufficiency recommended (See Appendix B, Table 7.)	1.1 hrs/ 7 hrs	• Bone marrow suppression: macrocytic anemia or neutropenia • Nausea, vomiting, headache, insomnia, asthenia • Nail pigmentation • Lactic acidosis/severe hepatomegaly with hepatic steatosis (rare but potentially life-threatening toxicity) • Hyperlipidemia • Insulin resistance/diabetes mellitus • Lipoatrophy • Myopathy
Combivir ZDV with 3TC	Combivir ZDV 300 mg + 3TC 150 mg	Combivir 1 tablet BID			
Trizivir ZDV with 3TC+ABC	Trizivir ZDV 300 mg + 3TC 150 mg + ABC 300 mg	Trizivir 1 tablet BID			

Appendix B, Table 2. Characteristics of Non-Nucleoside Reverse Transcriptase Inhibitors (NNRTIs) (Updated January 10, 2011)

Generic Name (abbreviation)/ Trade Name	Formulations	Dosing Recommendations (For dosage adjustment in renal or hepatic insufficiency, see Appendix B, Table 7.)	Elimination	Serum Half-life	Adverse Events (Also see Table 13)
Delavirdine (DLV)/ Rescriptor	100-, 200-mg tablets	400 mg TID (Four 100-mg tablets can be dispersed in >3 oz. of water to produce a slurry; 200-mg tablets should be taken as intact tablets.) Take without regard to meals Separate dose from antacids by 1 hour	CYP3A4 substrate and inhibitor; 51% excreted in urine (<5% unchanged) and 44% in feces	5.8 hrs	• Rash* • Increased transaminase levels • Nausea, headache
Efavirenz (EFV)/ Sustiva **Also available as**: Atripla EFV with FTC + TDF	• 50-, 200-mg capsules • 600-mg tablets Atripla EFV 600 mg + FTC 200 mg + TDF 300 mg	600 mg once daily at or before bedtime Take on an empty stomach to reduce side effects Atripla 1 tablet once daily at or before bedtime	Metabolized by CYPs 2B6 and 3A4 CYP3A4 mixed inducer/ inhibitor (more an inducer than an inhibitor)	40–55 hrs	• Rash* • Neuropsychiatric symptoms† • Increased transaminase levels • Hyperlipidemia • False-positive results reported with some cannabinoid and benzodiazepine screening assays • Teratogenic in nonhuman primates and potentially teratogenic in humans
Etravirine (ETR)/ Intelence	• 100-, 200-mg tablets	200 mg BID Take following a meal	CYP3A4, 2C9, and 2C19 substrate 3A4 inducer; 2C9 and 2C19 inhibitor	41 +/– 20 hrs	• Rash, including Stevens-Johnson syndrome* • Hypersensitivity reactions (HSRs) have been reported, characterized by rash, constitutional findings, and sometimes organ dysfunction, including hepatic failure • Nausea
Nevirapine (NVP)/ Viramune	• 200-mg tablets • 50-mg/5-mL oral suspension	200 mg once daily for 14 days (lead-in period); thereafter, 200 mg BID Take without regard to meals Repeat lead-in period if therapy is discontinued for >7 days In patients who develop mild to moderate rash without constitutional symptoms, continue lead-in period until rash resolves but no longer than 28 days total.	CYP450 substrate, inducer of 3A4 and 2B6; 80% excreted in urine (glucuronidated metabolites, <5% unchanged); 10% in feces	25–30 hrs	• Rash, including Stevens-Johnson syndrome* • Symptomatic hepatitis, including fatal hepatic necrosis, has been reported‡

* During clinical trials, NNRTI was discontinued because of rash among 7% of NVP-treated, 4.3% of DLV-treated, 1.7% of EFV-treated, and 2% of ETR-treated patients. Rare cases of Stevens-Johnson syndrome have been reported with all NNRTIs; the highest incidence was seen with NVP.

† Adverse events can include dizziness, somnolence, insomnia, abnormal dreams, confusion, abnormal thinking, impaired concentration, amnesia, agitation, depersonalization, hallucinations, and euphoria. Approximately 50% of patients receiving EFV may experience any of these symptoms. Symptoms usually subside spontaneously after 2–4 weeks, but may necessitate discontinuation of EFV in a small percentage of patients.

‡ Symptomatic, sometimes serious, and even fatal hepatic events (accompanied by rash in approximately 50% of cases) occur at significantly higher frequency in ARV-naïve female patients with pre-NVP CD4 counts >250 cells/mm^3 or in ARV-naïve male patients with pre-NVP CD4 counts >400 cells/mm^3. NVP should not be initiated in these patients unless the benefit clearly outweighs the risk. This toxicity has not been observed when NVP is given as single doses to mothers or infants for prevention of mother-to-child transmission of HIV.

Appendix B, Table 3. Characteristics of Protease Inhibitors (PIs) (Updated January 10, 2011)

Generic Name (abbreviation)/ Trade Name	Formulations	Dosing Recommendations (For dosage adjustment in hepatic insufficiency, see Appendix B, Table 7)	Elimination	Serum Half-life	Storage	Adverse Events (Also see Table 13)
Atazanavir (ATV)/ Reyataz	100-, 150-, 200-, 300-mg capsules	ARV-naïve patients: 400 mg once daily or (ATV 300 mg + RTV 100 mg) once daily With TDF or for ARV-experienced patients: (ATV 300 mg + RTV 100 mg) once daily With EFV in ARV-naïve patients: (ATV 400 mg + RTV 100 mg) once daily (For dosing recommendations with H_2 antagonists and proton pump inhibitor (PPIs), refer to Table 16a) Take with food	CYP3A4 inhibitor and substrate Dosage adjustment in hepatic insufficiency recommended (See Appendix B, Table 7.)	7 hrs	Room temperature (up to 25ºC or 77ºF)	• Indirect hyperbilirubinemia • PR interval prolongation: First degree symptomatic atrioventricular (AV) block reported. Use with caution in patients with underlying conduction defects or on concomitant medications that can cause PR prolongation. • Hyperglycemia • Fat maldistribution • Possible increased bleeding episodes in patients with hemophilia • Nephrolithiasis • Skin rash (20%) • Serum transaminase elevations • Hyperlipidemia (especially with RTV boosting)
Darunavir (DRV)/ Prezista	75-, 150-, 300-, 400-, 600-mg tablets	ARV-naïve patients or ARV-experienced patients with no DRV mutations: (DRV 800 mg + RTV 100 mg) once daily ARV-experienced patients with at least one DRV mutation: (DRV 600 mg + RTV 100 mg) BID Unboosted DRV is **not** recommended Take with food	CYP3A4 inhibitor and substrate	15 hrs (when combined with RTV)	Room temperature (up to 25ºC or 77ºF)	• Skin rash (10%): DRV has a sulfonamide moiety; Stevens-Johnson syndrome and erythrema multiforme have been reported. • Hepatotoxicity • Diarrhea, nausea • Headache • Hyperlipidemia • Serum transaminase elevation • Hyperglycemia • Fat maldistribution • Possible increased bleeding episodes in patients with hemophilia
Fosamprenavir (FPV)/ Lexiva (a prodrug of amprenavir [APV])	• 700-mg tablet • 50-mg/mL oral suspension	ARV-naïve patients: • FPV 1,400 mg BID or • (FPV 1,400 mg + RTV 100–200 mg) once daily or • (FPV 700 mg + RTV 100 mg) BID PI-experienced patients (once-daily dosing **not** recommended): • (FPV 700 mg + RTV 100 mg) BID With EFV: • (FPV 700 mg + RTV 100 mg) BID or • (FPV 1,400 mg + RTV 300 mg) once daily *Tablet*: Take without regard to meals (if not boosted with RTV tablet) *Suspension*: Take without food *FPV w/RTV tablet*: Take with meals	APV is a CYP3A4 substrate, inhibitor, and inducer Dosage adjustment in hepatic insufficiency recommended (See Appendix B, Table 7.)	7.7 hrs (APV)	Room temperature (up to 25ºC or 77ºF)	• Skin rash (12%–19%) – FPV has a sulfonamide moiety • Diarrhea, nausea, vomiting • Headache • Hyperlipidemia • Serum transaminase elevation • Hyperglycemia • Fat maldistribution • Possible increased bleeding episodes in patients with hemophilia • Nephrolithiasis

Appendix B, Table 3. Characteristics of Protease Inhibitors (PIs)
Page 2 of 3

Generic Name (abbreviation)/ Trade Name	Formulations	Dosing Recommendations (For dosage adjustment in hepatic insufficiency, see Appendix B, Table 7)	Elimination	Serum Half-life	Storage	Adverse Events (Also see Table 13)
Indinavir (IDV)/ Crixivan	100-, 200-, 400-mg capsules	800 mg every 8 hrs Take 1 hour before or 2 hours after meals; may take with skim milk or low-fat meal With RTV: (IDV 800 mg + RTV 100–200 mg) BID Take without regard to meals	CYP3A4 inhibitor and substrate Dosage adjustment in hepatic insufficiency recommended (See Appendix B, Table 7.)	1.5–2 hrs	Room temperature (15º–30ºC/ 59º–86ºF) Protect from moisture	• Nephrolithiasis • GI intolerance, nausea • Hepatitis • Indirect hyperbilirubinemia • Hyperlipidemia • Headache, asthenia, blurred vision, dizziness, rash, metallic taste, thrombocytopenia, alopecia, and hemolytic anemia • Hyperglycemia • Fat maldistribution • Possible increased bleeding episodes in patients with hemophilia
Lopinavir + Ritonavir (LPV/r)/ Kaletra	Tablets: (LPV 200 mg + RTV 50 mg) or (LPV 100 mg + RTV 25 mg) Oral solution: Each 5 mL contains (LPV 400 mg + RTV 100 mg) Oral solution contains 42% alcohol	LPV/r 400-mg/100-mg BID or LPV/r 800-mg/200-mg once daily Once-daily dosing is not recommended for patients with ≥3 LPV-associated mutations, pregnant women, or patients receiving EFV, NVP, FPV, NFV, carbamazepine, phenytoin, or phenobarbital. With EFV or NVP (PI-naïve or PI-experienced patients): LPV/r 500-mg/125-mg tablets BID (Use a combination of two LPV/r 200-mg/50-mg tablets + one LPV/r 100-mg/25-mg tablet to make a total dose of LPV/r 500 mg/125 mg.) or LPV/r 533-mg/133-mg oral solution BID *Tablet*: Take without regard to meals *Oral solution*: Take with food	CYP3A4 inhibitor and substrate	5–6 hrs	Oral tablet is stable at room temperature. Oral solution is stable at 2°–8°C (36°–46°F) until date on label and is stable when stored at room temperature (up to 25ºC or 77ºF) for 2 months.	• GI intolerance, nausea, vomiting, diarrhea • Pancreatitis • Asthenia • Hyperlipidemia (especially hypertriglyceridemia) • Serum transaminase elevation • Hyperglycemia • Insulin resistance/diabetes mellitus • Fat maldistribution • Possible increased bleeding episodes in patients with hemophilia • PR interval prolongation • QT interval prolongation and torsades de pointes have been reported; however, causality could not be established.
Nelfinavir (NFV)/ Viracept	• 250-, 625-mg tablets • 50-mg/g oral powder	1,250 mg BID or 750 mg TID May dissolve tablets in a small amount of water; once dissolved, patients should mix the cloudy liquid well and consume it immediately. Take with food	CYP2C19 and 3A4 substrate—metabolized to active M8 metabolite; CYP 3A4 inhibitor	3.5–5 hrs	Room temperature (15º–30ºC/ 59º–86ºF)	• Diarrhea • Hyperlipidemia • Hyperglycemia • Fat maldistribution • Possible increased bleeding episodes in patients with hemophilia • Serum transaminase elevation

Appendix B, Table 3. Characteristics of Protease Inhibitors (PIs)
Page 3 of 3

Generic Name (abbreviation)/ Trade Name	Formulations	Dosing Recommendations (For dosage adjustment in hepatic insufficiency, see Appendix B, Table 7)	Elimination	Serum Half-life	Storage	Adverse Events (Also see Table 13)
Ritonavir (RTV)/ Norvir	• 100-mg soft gel capsules • 100-mg tablets • 80-mg/mL oral solution Oral solution contains 43% alcohol	As pharmacokinetic booster for other PIs: 100–400 mg per day in 1–2 divided doses (refer to other PIs for specific dosing recommendations) *Tablet*: Take with food *Capsule and oral solution*: Take with food, if possible, to improve tolerability.	CYP3A4 >2D6 substrate; potent 3A4, 2D6 inhibitor	3–5 hrs	Refrigerate capsules Capsules can be left at room temperature (up to 25ºC or 77ºF) for up to 30 days. Tablets do not require refrigeration. Oral solution should **not** be refrigerated; store at room temperature 20º–25ºC (68º–77ºF).	• GI intolerance, nausea, vomiting, diarrhea • Paresthesias—circumoral and extremities • Hyperlipidemia (especially hypertriglyceridemia) • Hepatitis • Asthenia • Taste perversion • Hyperglycemia • Fat maldistribution • Possible increased bleeding episodes in patients with hemophilia
Saquinavir tablets and hard gel capsules (SQV)/ Invirase	• 500-mg tablets • 200-mg hard gel capsules	(SQV 1,000 mg + RTV 100 mg) BID Unboosted SQV is **not** recommended. Take with meals or within 2 hours after a meal	CYP3A4 inhibitor and substrate	1–2 hrs	Room temperature (15º–30ºC/ 59º–86ºF)	• GI intolerance, nausea, and diarrhea • Headache • Serum transaminase elevation • Hyperlipidemia • Hyperglycemia • Fat maldistribution • Possible increased bleeding episodes in patients with hemophilia • PR interval prolongation • QT interval prolongation, torsades de pointes have been reported. Patients with pre-SQV QT interval >450 msec should not receive SQV (See Table 5b.).
Tipranavir (TPV)/ Aptivus	• 250-mg capsules • 100-mg/mL oral solution	(TPV 500 mg + RTV 200 mg) BID Unboosted TPV is **not** recommended. *TPV taken with RTV **tablets**:* Take with meals *TPV taken with RTV **capsules** or **solution**:* Take without regard to meals	Cytochrome P450 3A4 inducer and substrate Net effect when combined with RTV (CYP 3A4, 2D6 inhibitor)	6 hrs after single dose of TPV/r	Refrigerate capsules. Capsules can be stored at room temperature (25ºC or 77ºF) for up to 60 days. Oral solution should **not** be refrigerated or frozen and should be used within 60 days after opening the bottle.	• Hepatotoxicity: Clinical hepatitis (including hepatic decompensation and hepatitis-associated fatalities) has been reported; monitor closely, especially in patients with underlying liver diseases. • Skin rash (3%–21%): TPV has a sulfonamide moiety; use with caution in patients with known sulfonamide allergy. • Rare cases of fatal and nonfatal intracranial hemorrhages have been reported. Risks include brain lesion, head trauma, recent neurosurgery, coagulopathy, hypertension, alcoholism,, use of anti-coagulant or anti-platelet agents including vitamin E. • Hyperlipidemia • Hyperglycemia • Fat maldistribution • Possible increased bleeding episodes in patients with hemophilia

Appendix B, Table 4. Characteristics of Integrase Inhibitor (Updated January 10, 2011)

Generic Name (abbreviation)/ Trade Name	Formulations	Dosing Recommendations (For dosage adjustment in hepatic insufficiency, see Appendix B, Table 7.)	Serum half-life	Route of Metabolism	Adverse Events (Also see Table 13)
Raltegravir (RAL)/ Isentress	400 mg tablets	400 mg BID With rifampin: 800 mg BID Take without regard to meals	~9 hrs	UGT1A1-mediated glucuronidation	• Nausea • Headache • Diarrhea • Pyrexia • CPK elevation, muscle weakness and rhabdomyolysis

Appendix B, Table 5. Characteristics of Fusion Inhibitor (Updated January 29, 2008)

Generic Name (abbreviation)/ Trade Name	Formulations	Dosing Recommendation	Serum half-life	Elimination	Storage	Adverse Events (Also see Table 13)
Enfuvirtide (T20)/ Fuzeon	• Injectable—supplied as lyophilized powder • Each vial contains 108 mg of T20; reconstitute with 1.1mL of sterile water for injection for delivery of approximately 90mg/1mL.	90 mg (1mL) subcutaneously BID	3.8 hrs	Expected to undergo catabolism to its constituent amino acids, with subsequent recycling of the amino acids in the body pool	Store at room temperature (up to 25ºC or 77ºF). Reconsti-tuted solution should be refrigerated at 2ºC–8ºC (36ºF–46Fº) and used within 24 hours.	• Local injection site reactions in almost 100% of patients (pain, erythema, induration, nodules and cysts, pruritus, ecchymosis) • Increased bacterial pneumonia • Hypersensitivity reaction (<1%): Symptoms may include rash, fever, nausea, vomiting, chills, rigors, hypotension, or elevated serum transaminases. Rechallenge is not recommended.

Appendix B, Table 6. Characteristics of CCR5 Antagonist (Updated January 29, 2008)

Generic Name (abbreviation)/ Trade Name	Formulation	Dosing Recommendations (For dosage adjustment in hepatic insufficiency, see Appendix B, Table 7.)	Serum Half-life	Elimination	Adverse Events (Also see Table 13)
Maraviroc (MVC)/ Selzentry	150-, 300-mg tablets	• **150 mg BID** when given with strong CYP3A inhibitors (with or without CYP3A inducers) including PIs (except TPV/r) • **300 mg BID** when given with NRTIs, T-20, TPV/r, NVP, RAL, and other drugs that are not strong CYP3A inhibitors or inducers • **600 mg BID** when given with CYP3A inducers, including EFV, ETR, etc. (without a CYP3A inhibitor) Take without regard to meals	14–18 hrs	CYP3A4 substrate	• Abdominal pain • Cough • Dizziness • Musculoskeletal symptoms • Pyrexia • Rash • Upper respiratory tract infections • Hepatotoxicity • Orthostatic hypotension

Appendix B, Table 7. Antiretroviral Dosing Recommendations in Patients with Renal or Hepatic Insufficiency (Updated January 10, 2011)

See reference section following tables for creatinine clearance (CrCl) calculation formulas and criteria for Child-Pugh classification.

Antiretrovirals Generic Name (abbreviation)/Trade Name	Usual Daily Dose (Refer to Appendix B Tables 1-6 for additional dosing information)	Dosing in Renal Insufficiency (Including with chronic ambulatory peritoneal dialysis [CAPD] and hemodialysis [HD])	Dosing in Hepatic Impairment
Nucleoside Reverse Transcriptase Inhibitors **Use of fixed-dose combination NRTI (+/- NNRTI) of Atripla, Combivir, Trizivir, or Epzicom is not recommended in patients with CrCl <50 mL/min. Use of Truvada is not recommended in patients with CrCl <30 mL/min.**			
Abacavir (ABC)/ Ziagen	300 mg PO BID	No dosage adjustment necessary	**Child-Pugh Score** — **Dose** 5–6 — 200 mg BID (use oral solution) > 6 — Contraindicated
Didanosine enteric coated (ddI)/ Videx EC	**Body weight ≥60 kg**: 400 mg PO once daily **Body weight <60 kg**: 250 mg PO once daily	**Dose (once daily)** **CrCl (mL/min)** — **≥60 kg** — **<60 kg** 30–59 — 200 mg — 125 mg 10–29 — 125 mg — 125 mg <10, HD, CAPD — 125 mg — use oral solution	No dosage adjustment necessary
Didanosine oral solution (ddI)/ Videx	**Body weight ≥60 kg**: 200 mg PO BID or 400 mg PO once daily **Body weight <60 kg**: 250 mg PO once daily or 125 mg PO BID	**Dose (once daily)** **CrCl (mL/min)** — **≥60 kg** — **<60 kg** 30–59 — 200 mg — 150 mg 10–29 — 150 mg — 100 mg <10, HD, CAPD — 100 mg — 75 mg	No dosage adjustment necessary
Emtricitabine (FTC)/ Emtriva	200mg oral capsule PO once daily; or 240 mg (24 mL) oral solution PO once daily	**Dose** **CrCl (mL/min)** — **Capsule** — **Solution** 30–49 — 200 mg q48h — 120 mg q24h 15–29 — 200 mg q72h — 80 mg q24h <15 or HD — 200 mg q96h — 60 mg q24h Take dose after HD session on dialysis days	No dosage recommendation
Lamivudine (3TC)/ Epivir	300 mg PO once daily; or 150 mg PO BID	**CrCl (mL/min)** — **Dose** 30–49 — 150 mg q24h 15–29 — 1 x 150 mg, then 100 mg q24h 5–14 — 1 x 150 mg, then 50 mg q24h <5 or HD — 1 x 50 mg, then 25 mg q24h Take dose after HD session on dialysis days	No dosage adjustment necessary
Stavudine (D4T)/ Zerit	**Body weight ≥60 kg**: 40 mg PO BID **Body weight <60 kg**: 30 mg PO BID	**Dose** **CrCl (mL/min)** — **≥60 kg** — **<60 kg** 26–50 — 20 mg q12h — 15 mg q12h 10–25 or HD — 20 mg q24h — 15 mg q24h Take dose after HD session on dialysis days	No dosage recommendation
Tenofovir (TDF)/ Viread	300 mg PO once daily	**CrCl (mL/min)** — **Dose** 30–49 — 300 mg q48h 10–29 — 300 mg twice weekly <10 not on HD — no recommendation HD — 300 mg q7d Take dose after HD session on dialysis days	No dosage adjustment necessary
Emtricitabine (FTC) + **Tenofovir** (TDF)/ Truvada	1 tablet PO once daily	**CrCl (mL/min)** — **Dose** 30–49 — 1 tablet q48h <30 or HD — not recommended	No dosage recommendation
Zidovudine (AZT, ZDV)/ Retrovir	300 mg PO BID	**CrCl (mL/min)** — **Dose** < 15 or HD — 100 mg TID or 300 mg once daily	No dosage recommendation

Appendix B, Table 7. Antiretroviral Dosing Recommendations in Patients with Renal or Hepatic Insufficiency

Antiretrovirals Generic Name (abbreviation)/ Trade Name	Daily Dose	Dosing in Renal Insufficiency (Including with chronic ambulatory peritoneal dialysis [CAPD] and hemodialysis [HD])	Dosing in Hepatic Impairment
Non-Nucleoside Reverse Transcriptase Inhibitors			
Delavirdine (DLV)/ Rescriptor	400 mg PO TID	No dosage adjustment necessary	No dosage recommendation; use with caution in patients with hepatic impairment
Efavirenz (EFV)/ Sustiva	600 mg PO at or before bedtime	No dosage adjustment necessary	No dosage recommendation; use with caution in patients with hepatic impairment
Efavirenz (EFV) + **Emtricitabine** (FTC) + **Tenofovir** (TDF)/ Atripla	1 tablet PO once daily	Atripla not recommended if CrCl <50 mL/min	
Etravirine (ETR)/ Intelence	200 mg PO BID	No dosage adjustment necessary	Child-Pugh Class A or B: no dosage adjustment Child-Pugh Class C: no dosage recommendation
Nevirapine (NVP)/ Viramune	200 mg PO BID	HD patients: limited data; no dosage recommendation	Child-Pugh Class B or C: contraindicated
Protease Inhibitors			
Atazanavir (ATV)/ Reyataz	400 mg PO once daily or (ATV 300 mg + RTV 100 mg) PO once daily	No dosage adjustment for patients with renal dysfunction not requiring HD ARV-naïve patients on HD: (ATV 300 mg + RTV 100 mg) once daily ARV-experienced patients on HD: ATV or RTV-boosted ATV not recommended	**Child-Pugh Score** **Dose** 7–9 300 mg once daily >9 not recommended RTV boosting is **not** recommended in patients with hepatic impairment (Child-Pugh Score ≥7).
Darunavir (DRV)/ Prezista	(DRV 800 mg + RTV 100 mg) PO once daily (ARV-naïve patients) or (DRV 600 mg + RTV 100 mg) PO BID	No dosage adjustment necessary	Mild to moderate hepatic impairment: no dosage adjustment Severe hepatic impairment: not recommended
Fosamprenavir (FPV)/ Lexiva	1,400 mg PO BID or (FPV 1,400 mg + RTV 100–200 mg) PO once daily or (FPV 700 mg + RTV 100 mg) PO BID	No dosage adjustment necessary	**Child-Pugh Score** **Dose** PI-naïve patients only: 5–9 700 mg BID 10–15 350 mg BID PI-naïve or PI-experienced patients: 5–6 700 mg BID + RTV 100 mg once daily 7–9 450 mg BID + RTV 100 mg once daily 10–15 300 mg BID + RTV 100 mg once daily
Indinavir (IDV)/ Crixivan	800 mg PO q8h	No dosage adjustment necessary	Mild to moderate hepatic insufficiency because of cirrhosis: 600 mg q8h
Lopinavir/ritonavir (LPV/r) Kaletra	400/100 mg PO BID or 800/200 mg PO once daily	Avoid once daily dosing in patients on HD	No dosage recommendation; use with caution in patients with hepatic impairment
Nelfinavir (NFV)/ Viracept	1,250 mg PO BID	No dosage adjustment necessary	Mild hepatic impairment: no dosage adjustment Moderate to severe hepatic impairment: do not use
Ritonavir (RTV)/ Norvir	As a PI-boosting agent: 100–400 mg per day	No dosage adjustment necessary	Refer to recommendations for the primary PI
Saquinavir (SQV)/ Invirase	(SQV 1,000 mg + RTV 100 mg) PO BID	No dosage adjustment necessary	Mild to moderate hepatic impairment: use with caution Severe hepatic impairment: contraindicated
Tipranavir (TPV)/ Aptivus	(TPV 500 mg + RTV 200 mg) PO BID	No dosage adjustment necessary	Child-Pugh Class A: use with caution Child-Pugh Class B or C: contraindicated

Appendix B, Table 7. Antiretroviral Dosing Recommendations in Patients with Renal or Hepatic Insufficiency

Antiretrovirals Generic Name (abbreviation)/ Trade Name	Daily Dose	Dosing in Renal Insufficiency	Dosing in Hepatic Impairment
Fusion Inhibitor			
Enfuvirtide (T20)/ Fuzeon	90 mg subcutaneous BID	No dosage adjustment necessary	No dosage adjustment necessary
CCR5 Antagonist			
Maraviroc (MVC)/ Selzentry	The recommended dose differs based on concomitant medications because of drug interactions. See **Appendix B, Table 6** for detailed dosing information.	**CrCl <30 mL/min or HD** Without potent CYP3A inhibitors or inducers: 300 mg BID; reduce to 150 mg BID if postural hypotension occurs With potent CYP3A inducers or inhibitors: not recommended	No dosage recommendations. Concentrations will likely be increased in patients with hepatic impairment.
Integrase Inhibitor			
Raltegravir (RAL)/ Isentress	400 mg BID	No dosage adjustment necessary	Mild to moderate hepatic insufficiency: no dosage adjustment necessary Severe hepatic insufficiency: no recommendation

Creatinine Clearance Calculation	
Male: $\frac{(140 - \text{age in years}) \times \text{weight (kg)}}{72 \times \text{Serum Creatinine}}$	Female: $\frac{(140 - \text{age in years}) \times \text{weight (kg)} \times 0.85}{72 \times \text{Serum Creatinine}}$

Child-Pugh Score			
Component	**Points Scored**		
	1	**2**	**3**
Encephalopathy*	None	Grade 1–2	Grade 3–4
Ascites	None	Mild or controlled by diuretics	Moderate or refractory despite diuretics
Albumin	>3.5 g/dL	2.8–3.5 g/dL	<2.8 g/dL
Total bilirubin or	<2 mg/dL (<34 μmol/L)	2–3 mg/dL (34 μmol/L to 50 μmol/L)	>3 mg/dL (>50 μmol/L)
Modified total bilirubin†	<4 mg/dL	4–7 mg/dL	>7 mg/dL
Prothrombin time (seconds prolonged) or	<4	4–6	>6
International normalized ratio (INR)	<1.7	1.7–2.3	>2.3

* Encephalopathy Grades
Grade 1: Mild confusion, anxiety, restlessness, fine tremor, slowed coordination
Grade 2: Drowsiness, disorientation, asterixis
Grade 3: Somnolent but rousable, marked confusion, incomprehensible speech, incontinence, hyperventilation
Grade 4: Coma, decerebrate posturing, flaccidity
† Modified total bilirubin used to score patients who have Gilbert's syndrome or who are taking indinavir or atazanavir

Child-Pugh Classification	Total Score*
Class A	5–6 points
Class B	7–9 points
Class C	>9 points

* Sum of points for each component

Draft United Kingdom National Guideline for the Diagnosis and Treatment of Gonorrhoea in Adults 2010 *v*5

Clinical Effectiveness Group, British Association of Sexual Health and HIV

Author and centre Chris Bignell, Consultant in Genitourinary Medicine, Nottingham University Hospitals NHS Trust

Editor Mark FitzGerald

Review Date 2015

Changes since 2005 Guideline

- Nucleic Acid amplification tests (NAATs) can be used for genital specimens but require supplementary testing if used in low prevalence areas.
- Dual testing for gonorrhoea and Chlamydia can be done using NAATs
- NAATs are more sensitive than culture in the rectum and pharynx but should be confirmed by a supplementary test
- Quinolones are no longer routinely recommended for treatment
- Indications for test of cure are clarified

DRAFT

Introduction

The main purpose of this guideline is to offer recommendations on the diagnosis, treatment and health promotion principles for the effective management of anogenital and pharyngeal gonorrhoea. It is aimed primarily at people aged 16 years and older presenting to services offering level 3 care in STI management within the United Kingdom. However, the principles of the recommendations could be adopted at all levels.

Editorial independence – this guideline was commissioned and edited by the Clinical Effectiveness Group (CEG) of the British Association for Sexual Health and HIV (BASHH). No external funding was sought or obtained.

Rigour of development – The CEG's framework for guideline development is outlined at bash.org/guidelines. This guideline has been updated by reviewing the previous guideline (2005) and medical literature since its publication. A MEDLINE search was done of published articles in any language for the years 2005-2009 using the subject headings *'gonorrhea'* and *'Neisseria gonorrheae'*. All enties in the English language or with abstracts in English were viewed because of the paucity of 'clinical trials' or 'reviews'. The Cochrane Database of Systematic Reviews, Database of Abstracts of Reviews of Effectiveness, and Cochrane Controlled Trials Register were reviewed using the textword 'gonorrhoea' and all entries considered. Abstracts from meetings in the relevant period were handsearched and considered. The draft guideline was appraised with the AGREE instrument, posted on the BASHH website for consultation for 3 months, and piloted in a sample of clinics.

Aetiology

Gonorrhoea is the condition of being infected with the Gram-negative diplococcus *Neisseria gonorrhoeae.* The primary sites of infection are the mucous membranes of the urethra, endocervix, rectum, pharynx and conjunctiva. Transmission is by direct inoculation of infected secretions from one mucous membrane to another.

Clinical features.

Symptoms. [1 - 3]
Men :

- urethral infection commonly causes urethral discharge (>80%) and/or dysuria (>50%), starting within 2-5 days of exposure.
- urethral infection can be asymptomatic (<10%).
- rectal infection is usually asymptomatic but may cause anal discharge (12%) or perianal/anal pain or discomfort (7%).
- pharyngeal infection is usually asymptomatic (>90%).

Women:

- infection at the endocervix is frequently asymptomatic (up to 50%).
- increased or altered vaginal discharge is the commonest symptom (up to 50%).
- lower abdominal pain may be present (up to 25%).
- urethral infection may cause dysuria (12%) but not frequency.
- gonorrhoea is a rare cause of intermenstrual bleeding or menorrhagia.
- rectal infection more frequently develops by transmucosal spread of infected genital secretions than from anal intercourse and is usually asymptomatic.
- pharyngeal infection is usually asymptomatic (>90%).

Neisseria gonorrhoeae may co-exist with other genital mucosal pathogens, notably *Chlamydia trachomatis, Trichomonas vaginalis,* and *Candida albicans* **.** If symptoms are present, they may be attributable to the co-infecting pathogen.

Signs. [1,2]
Men:

- a mucopurulent or purulent urethral discharge is commonly evident.
- rarely, epididymal tenderness/swelling or balanitis may be present.

DRAFT

Women:

- mucopurulent endocervical discharge and easily induced endocervical bleeding (<50%). [Note: mucopurulent endocervical discharge is not a sensitive predictor of cervical infection (<50%).]
- pelvic/lower abdominal tenderness (<5%).
- commonly, no abnormal findings are present on examination.

Complications.

Transluminal spread of *N. gonorrhoeae* from the urethra or endocervix may occur to cause epididymo-orchitis or prostatitis in men and pelvic inflammatory disease in women. Haematogenous dissemination may also occur from infected mucous membranes to cause skin lesions, arthralgia, arthritis and tenosynovitis. Disseminated gonoccal infection. There are no recent studies quantifying the risk of developing complicated gonococcal infection but reporting from GU Medicine clinics in the UK indicate they are uncommon [4].

Diagnosis

- This guideline should be read in conjunction with Health Protection Agency 'Guidance for Gonorrhoea Testing in England and Wales' and BASHH guidelines on /testing for STIs/ gonorrhoea [5,6].
- The diagnosis of gonorrhoea is established by the identification of *N. gonorrhoeae* at an infected site.
- The approach and method used to test for gonorrhoea will be influenced by the clinical setting, storage and transport system to the laboratory, local prevalence of infection and the range of tests available in the laboratory.
- No test for gonorrhoea offers 100% sensitivity and specificity [5,7,8,9].
- Microscopy (x1000) of Gram stained genital specimens allows direct visualization of *N. gonorrhoeae* as monomorphic Gram negative diplococci within polymorphonuclear leukocytes. It offers good sensitivity (90-95%) in men with urethral discharge and is recommended to facilitate immediate diagnosis in symptomatic men (level of evidence III; grade C recommendation). Microscopy of urethral smears in asymptomatic men is less sensitive (50-75%)[1]. In women, microscopy has poor sensitivity for the identification of gonoccal infection - 37-50% for endocervical smears and 20% for urethral smears [2]. Microscopy is not recommended for urethral smears in women or for detecting asymptomatic rectal infection because of low sensitivity (level of evidence III; grade C recommendation). Microscopy is not appropriate for diagnosing gonorrhoea in pharyngeal specimens.

- Specific identification of *N. gonorrhoeae* can be achieved by nucleic acid amplification tests (NAATs) or culture. NAATs are generally more sensitive than culture and offer testing on a wider range of specimen types [5,8-12,]. NAATs show high sensitivity (>96%) in both symptomatic and asymptomatic infection [10, 12]. They show equivalent sensitivity in urine and urethral swab specimens from men [13] and in vaginal and endocervical swabs from women [14]. The test sensitivity in female urine is significantly lower and urine is not a recommended specimen in women [5,12,15,] (level of evidence II; grade B recommendation).

DRAFT

- Persons undergoing testing for genital tract gonorrhoea are usually also tested for infection with *Chlamydia trachomatis*. NAATs are the standard test methodology for *C. trachomatis* testing and commercial tests offer dual capability to also test for *N. gonorrhoeae* on the same sample. When testing for genital tract infection, a dual NAAT for both pathogens maximizes sensitivity and operational ease of specimen collection, transport and processing.

- NAATs are significantly more sensitive than culture for detecting *N. gonorrhoeae* in the rectum and pharynx although are not yet approved for use at these sites [16-20]. Commercially available NAATs differ in their cross-reactivity to commensal *Neisseria* species which may be present at significant levels at these sites, particularly in the pharynx [21]. At present it is recommended that reactive specimens from the rectum and pharynx are confirmed by supplementary testing, ie using a different target (level of evidence III; grade C recommendation) [5,7,22].

- Culture continues to offer a specific, sensitive and cheap diagnostic test at genital sites. It allows confirmatory identification and antimicrobial susceptibility testing, which is of increasing importance as antimicrobial resistance to *N. gonorrhoeae* continues to evolve. Selective culture media containing antimicrobials are recommended to reduce contamination [23] (level of evidence II; grade B recommendation).

- Whatever the adopted testing approach, positive test results should give a positive predictive value of >90%. In areas of low gonorrhoea prevalence the use of NAATs may require supplementary testing [5,7,22]. Clinicians need to be familiar with the test performance of NAATs and be able to interpret results in their clinical setting [24,25].

<u>Specimen collection</u>.

Men:
A first pass urine is the preferred sample for NAAT testing [7,10,13,15]. Microscopy and culture require a urethral/meatal swab specimen. The collection and testing of rectal and pharyngeal swab specimens should be directed by sexual history, symptoms at these sites and also considered in men who receive oral-anal or digital-anal contact [26].

Women:
Vaginal or endocervical swab specimens are equally sensitive for detecting *N. gonorrhoeae* by NAAT testing [14]. Culture requires an endocervical and urethral swab specimen. Urine is a suboptimal sample for the detection of *N. gonorrhoeae* in women [5,7,9,12,15]. The collection and testing of rectal and pharyngeal swab specimens should be directed by sexual history, symptoms at these sites and also considered in women whose are sexual contacts of gonorrhoea.

- For culture, direct plating of genital samples and use of transport media with prompt laboratory plating both give acceptable results [22] (evidence level IV).

DRAFT

- Data is lacking on the sensitivity of a single set of tests to identify infection with *N. gonorrhoeae*. The use of a single endocervical or vulvovaginal sample will identify 90-95 % of women with gonococcal infection [2,27]. Women with *N. gonorrhoeae* infection often have infection at multiple sites [28]. A minority of MSM with gonorrhoea have infection at multiple sites and all exposed sites need sampling [18].
- To confidently exclude infection in patients who attend within three days of sexual contact, a second set of tests should be considered if epidemiological treatment with effective antimicrobial therapy is not given [29] (evidence level IV, recommendation level C). Conventionally this would be 14 days after contact.

Management.

General Advice.

- Patients should be given a detailed explanation of their condition with particular emphasis on the long-term implications for the health of themselves and their partner(s). This should be reinforced with clear and accurate written information (level of evidence IV; grade C recommendation).
- Patients should be advised to abstain from sexual intercourse until they and their partner(s) have completed treatment (level of evidence IV; grade C recommendation).

Further Investigation.

- Screening for coincident sexually transmitted infections should routinely be performed in patients with or at risk of gonorrhoea (evidence level III, recommendation level C).

Treatment.

Indications for therapy (level of evidence IV; grade C recommendation)

- Identification of intracellular Gram-negative diplococci on microscopy of a smear from the genital tract.
- a positive culture for *N. gonorrhoeae* from any site.
- a positive NAAT for *N. gonorrhoeae* from any site. Supplementary testing is recommended if positive predictive value of the test is < 90% [5,7,21].
- recent sexual partner (s) of confirmed cases of gonococcal infection,
- consider offering on epidemiological grounds following sexual assault.

Recommended treatments [30-38].

Uncomplicated anogenital infection in adults:

- Ceftriaxone 250mg IM as a single dose. (level of evidence 1b; grade A recommendation)
  or
- Cefixime 400mg oral as a single dose. (level of evidence 1b; grade A recommendation)
  or

DRAFT

- Spectinomycin* 2g IM as a single dose. (level of evidence 1b; grade A recommendation)

- *N. gonorrhoeae* has progressively acquired reduced sensitivity and resistance to many classes of antimicrobials. Published trials of gonorrhoea treatment reflect clinical efficacy in past eras of antimicrobial sensitivity. Surveillance data in the UK shows significant levels of *N. gonorrhoeae* resistance to penicillin (24% in 2007), tetracyclines (60% in 2007) and ciprofloxacin (28% in 2008)[39-41]. High-level azithromycin resistance (MIC >256 mg/L) was observed in 2007 in the UK [42]. In 2008, decreased susceptibility to cefixime (MIC ≥ 0.25mg/L) was observed at 1.5% and isolates with decreased susceptibility to ceftriaxone (MIC ≥ 0.125mg/L) were also identified[40]. Most resistant infections are acquired in the UK.
- The increasing recognition of multidrug resistant *N. gonorrhoeae* has been the driving force for the recommendation of extended spectrum cephalosporins as the preferred treatment of gonorrhea[43].
- Observations in Asia have raised serious concerns over the adequacy of the 400mg cefixime for the treatment of genital tract gonorrhoea. Repeated treatment failures have been reported with cefixime and other oral extended spectrum cephalosporins[43-44].

*Spectinomycin was not being manufactured in 2010 so may not be obtainable.

Alternative regimens

Clinicians using alternative regimens for the treatment of gonorrhoea are recommended to regularly review local and national trends in gonococcal antimicrobial resistance.

- Other single dose cephalosporin regimes, notably Cefotaxime 500mg IM as a single dose. (level of evidence Ib; grade A recommendation)
  or Cefoxitin 2g IM as a single dose plus probenecid* 1g oral.
  Alternative injectable or oral cephalosporins offer no advantage in terms of efficacy and pharmokinetics over ceftriaxone or cefixime [34].

- Cefpodoxime is an alternative oral third generation cephalosporin that as a single dose of 200mg oral is licensed for the treatment of uncomplicated gonorrhoea [45]. Published trial data are limited, but in view of its less favourable pharmokinetics than cefixime and suboptimal efficacy against pharyngeal infection, it should be used with caution at a dose of 400mg. (level of evidence II; grade C recommendation).

- Quinolones cannot generally be recommended for the treatment of gonorrhoea because of the high prevalence of quinolone resistance worldwide [40,41,46]. When an infection is known before

DRAFT

treatment to be quinolone sensitive ciprofloxacin 500mg oral as single dose or ofloxacin 400mg oral as single dose have proven efficacy (level of evidence Ib; grade A recommendation) [37,47].

- High dose azithromycin (2.0g as a single dose) has shown acceptable efficacy in clinical trials, but was associated with high gastrointestinal intolerance[48]. The clinical efficacy of azithromycin does not always correlate with *in-vitro* sensitivity testing [49-50] and high-level azithromycin resistance has been observed in the UK [42]. A single dose of azithromycin 1.0g is not recommended as treatment for gonorrhea (level of evidence II; grade C recommendation).

- The alternative treatment regimens listed do not comprise all effective treatment regimens, but reflect clinical practice in the UK.

DRAFT

Treatment of complicated infections

Gonococcal pelvic inflammatory disease (PID)

IM ceftriaxone 250 mg stat
Or
IM cefoxim 2g stat with oral Probenecid 1 g
followed by oral Doxycycline 100 mg bd plus Metronidazole 400 mg bd for 14 days
(see PID guidelines www.bashh.org.uk)

Gonococcal Epididymo-orchitis

IM Ceftriaxone 250 mg plus Doxycycline 100 mg bd for 10-14 days
(see Epididymoorchitis guideline www.bashh.org.uk)

Gonococcal Conjunctivitis

- Systemic antibiotic therapy as for genital infection
- Saline/water irrigation of eye as required (grade C recommendation)

Disseminated Gonococcal Infection (DGI) (grade C recommendation)

Ceftriaxone 1g IM or IV every 24 hours
Or
Cefotaxime 1 g IV every 8 hours
Or
Ciprofloxacin 500 mg IV every 12 hours
Or
Spectinomycin 2g IM every 12 hours

Therapy should continue for 7 days but may be switched 24-48 hours after symptoms improve to one of the following oral regimes:

Ciprofloxacin 500 mg twice daily
Or
Ofloxacin 400 mg twice daily
Or
Cefixime 400 mg twice daily

Allergy.

Third-generation cephalosporins show negligible cross-allergy with penicillins [51]. Contraindications to the administration of ceftriaxone are hypersensitivity to any cephalosporin or previous immediate and/or severe hypersensitivity reaction to a penicillin or other beta-lactam drug [52]. Recommended treatments for patients giving a history of such hypersensitivity:

- Spectinomycin* 2g IM as a single dose (level of evidence Ib; grade A recommendation). May not be obtainable (see above)

or

- Azithromycin 2.0g as a single oral dose (level of evidence Ib; grade B recommendation)

or

- Ciprofloxacin 500mg orally as a single dose when the infection is known or anticipated to be quinolone sensitive.

Pregnancy and Breastfeeding.

Pregnant and breast-feeding women should not be treated with quinolone or tetracycline antimicrobials.
Azithromycin: manufacturer advises use only if adequate alternatives are not available.
Pregnancy does not diminish treatment efficacy.

Recommended Regimes [53-55]

- Ceftriaxone 250mg IM as a single dose. (level of evidence Ib; grade A recommendation)

or

- Cefixime 400mg oral as a single dose. (level of evidence Ib;grade A recommendation)

or

- Spectinomycin* 2g IM as a single dose. (level of evidence Ib; grade A recommendation).

Pharyngeal infection.

DRAFT

Single-dose antimicrobials treatments have in general demonstrated lower efficacy (≤ 90%) in eradicating *N. gonorrhoeae* from the pharynx than in eradicating genital infection[31,56].

Recommended treatments [31,56]

- Ceftriaxone 250mg IM as a single dose (level of evidence Ib; grade B recommendation)

or

- Ciprofloxacin 500mg orally as a single dose if *N. gonorrhoeae* known to be quinolone sensitive (level of evidence Ib; grade B recommendation)

or

- Ofloxacin 400mg orally as a single dose if *N. gonorrhoeae* known to be quinolone sensitive. (level of evidence Ib; grade B recommendation).

Single dose treatment with spectinomycin has poor efficacy in eradicating gonococcal infection of the pharynx [31].

HIV Infection

Treatment for gonorrhoea in HIV infected individuals is the same as in those who are HIV negative

Co-infection with *Chlamydia trachomatis*

Genital infection with *C. trachomatis* commonly accompanies genital gonococcal infection (35% of heterosexual men and 41% of women with gonorrhea, GRASP 2008) [40]. Testing for *C. trachomatis* should routinely be performed on all adults with gonorrhoea or treatment given to eradicate possible co-infection [29,38] (level of evidence IV; grade C recommendation).

Sexual partners.

Partner notification should be pursued in all patients identified with gonococcal infection, preferably by a trained health adviser in GU Medicine. Action and outcomes should be documented[57]. Partner notification should follow national recommendations[58]:

- Male patients with symptomatic urethral infection should notify all partners with whom they had sexual contact within the preceding 2 weeks or their last partner if longer ago.
- Patients with infection at other sites or asymptomatic infection should notify all partners within the preceding 3 months.

Sex partners should be offered testing and treated epidemiologically for gonorrhoea (level of evidence IV; recommendation level C).

Follow up and test of cure.

Assessment after treatment may be helpful (level of evidence IV; grade C recommendation):

- to confirm compliance with treatment,

DRAFT

- to ensure resolution of symptoms,
- to enquire about adverse reactions,
- to take a sexual history to explore the possibility of re-infection,
- to pursue partner notification and health promotion.

A test of cure is not routinely necessary for anogenital infection if a recommended treatment has been administered [59-60]. Indications for test of cure include (level of evidence IV; grade C recommendation):

- Persistence of symptoms
- Re-exposure to infection
- When there is possible antimicrobial resistance to the therapy given
- Pharyngeal infection

If symptoms or signs persist after treatment, test of cure with culture is recommended to test for antimicrobial resistance.
(evidence level IV, recommendation C).
All treatments are less effective at eradicating pharyngeal infection [56] and test of cure is recommended following treatment of infection at this site (Level of evidence III; recommendation C).
If a test of cure is performed, culture tests should be performed at least 72 hours after completion of antimicrobial therapy [23] There is currently insufficient evidence to determine the best time to conduct a test of cure with NAAT's, but 3 weeks seems reasonable[61].
Infection identified after treatment more commonly indicates reinfection rather than treatment failure [3,60].

Auditable Outcome Measures

- All patients with gonorrhoea should be screened for genital infection with *Chlamydia trachomatis* or receive presumptive treatment for this infection.

- All patients identified with gonorrhoea should have at least one documented interview with a health adviser in GU Medicine or other health professional trained in partner notification and their action documented.

- All patients identified with gonorrhoea should have a record made of the outcome of the agreed contact action.

- All patients identified with gonorrhoea should be offered written information about sexually transmitted infections and their prevention.

- For every case of gonorrhoea the number of sexual contacts whose attendance was verified by a healthcare worker, within four weeks of the date of the first partner notification interview, should be at least 0.6. In some large cities this may be unachievable and a lower rate may need to be determined locally. [62-63]

DRAFT

Organisational and Financial Considerations

Whilst the treatments recommended differ in price, the importance of achieving a cure is so great that cost should not be a factor in chosing the most effective agent.

In some clinics, staffing levels and facilities may preclude the use of injectable antibiotics.

Qualifying statement

Decisions to follow these recommendations must be based on professional clinical judgement, consideration of individual patient circumstances and available resources. All possible care has been undertaken to ensure specification of the correct dosage of medication and route of administration. However, it remains the responsibility of the prescribing clinician to ensure the accuracy and appropriateness of the medication they prescribe.

Acknowledgments.

We wish to thank the following for their valuable contributions to this Guideline: members of the CEG, Cathy Ison, members of the National Audit Group, and the members of BASHH who made comments during the web-based consultation.

DRAFT

Gonorrhoea patient information leaflet

British Association for Sexual Health and HIV 2010

Gonorrhoea - the basics

- It is a curable sexually transmitted infection (STI) caused by the bacterium *Neisseria gonorrhoeae.*
- Gonorrhoea can infect the cervix (neck of womb), urethra (water passage) the uterus (womb), fallopian tubes, ovaries, testicles, rectum (anus), throat and sometimes the eyes.
- Men commonly notice a discharge from the tip of the penis but most women will not notice anything wrong.
- Prompt treatment is recommended to prevent more serious problems:
    - In women the spread of infection to the reproductive organs may lead to infertility
    - In men the spread of infection to the testicles leading to pain and swelling.
- Testing is available at any specialised sexual health or Genitourinary Medicine (GUM) clinic, and in some GP surgeries and contraceptive services.
- Gonorrhoea is resistant to many commonly used antibiotics. You need to be tested in a specialised sexual health service to ensure you receive the correct treatment.
- If you have gonorrhoea we recommend that you should have routine tests for other sexually transmitted infections including chlamydia, trichomonas, syphilis and HIV.

How common is gonorrhoea?

- It is the second most common bacterial STI in the UK.
- It is found most frequently in young people under the age of 25 years, in men who have sex with men and in people living in large cities.

How do you catch gonorrhoea?

- Gonorrhoea is passed on through:
    - unprotected vaginal, anal or oral sex (or sharing sex toys) with someone that has gonorrhoea
    - from an infected mother to her baby at birth
    - sometimes from genitals to fingers to eyes where it may cause an eye infection (conjunctivitis)
- Gonorrhoea cannot be caught by kissing, or from swimming pools, saunas or toilet seats.

What would I notice if I had gonorrhoea?

- **Women** may not notice anything wrong but they can still pass the infection onto their partner.
    - Infection usually starts in the cervix (neck of the womb) and can then spread internally to the uterus (womb), fallopian tubes and ovaries. Some women may notice one or more of the following:
        - bleeding between periods or after sex
        - lower abdominal pain particularly during sex
        - 'cystitis' or burning pain when passing urine
        - increased vaginal discharge
- **Men** will usually notice:
    - a discharge from the tip of the penis
    - a burning pain when passing urine
- Symptoms in men usually appear within 2-5 days of catching the infection.
- Infections in the throat or rectum usually go unnoticed**.**

How do I get tested for gonorrhoea?

- In **women**
    - If you have symptoms it is best if a swab is taken from the cervix (neck of the womb) by a doctor or nurse during an internal examination
    - If you do not have symptoms a self-taken swab can be taken from the entrance to the vagina

DRAFT

- In **men**
    - If you have a discharge a doctor or nurse will take a swab from the tip of the penis
    - If you do not have any symptoms a urine sample will be collected – but you should not have passed urine for at least a 1 hour
- Occasionally swabs may also be taken from the throat, rectum and eye.
- Some results for gonorrhoea may be available during your first visit (by looking at the samples under a microscope).
- You will be informed about how you will receive your final results before leaving the clinic.

How is gonorrhoea treated?

- Gonorrhoea can be easily treated with a single dose of an antibiotic – either by mouth or by injection.
- Occasionally a second course of antibiotics are needed if your symptoms don't go away or you are found to have a resistant strain of gonorrhoea.
- Treatment for chlamydia is commonly prescribed at the same time as up to 40% of people will also be infected with chlamydia.
- All treatments from sexual health clinics are free and are given to you in the clinic.

Important information about your treatment

- The antibiotics are highly effective - but you need to wait 7 days before having sex again to give the antibiotics time to work.
- The antibiotics may interfere with your contraceptive pill, ring or patch and make it less effective – the doctor or nurse will advise you what to do. (The implant, coil and Depo Provera injection are not effected)

What about my partner?

- Gonorrhoea is a sexually transmitted infection so it is likely that your current partner has it too.
- It is important that all current sexual partners attend a sexual health clinic to be tested and treated before resuming sex again.
- The clinic can contact your partners anonymously for you if you wish.
- Some of your previous partners may also need treatment – you will be advised about this.

When can I have sex again?

- You must not have sex again both you and your partner have taken your treatment and waited 7 days (this includes oral sex and sex with condoms).
- Sometimes you may be advised to have another test to check the gonorrhoea has gone completely – in this case it is important not to have sex until you receive your final result.

What happens if my gonorrhoea is left untreated?

- In **women:**
    - Gonorrhoea may spread internally from the cervix (neck of the womb) to the uterus (womb), and then up into the fallopian tubes and ovaries leading to pelvic infection and pain – a condition called Pelvic Inflammatory Disease (PID) (LINK to PID)
    - PID can lead to scarring of the fallopian tubes and ectopic pregnancy and/or infertility.
- In **men:**
    - Gonorrhoea can spread from the urethra (water passage) to the testicles and cause pain. Very rarely this may affect fertility.
- In both men and women gonorrhoea can spread to the blood (septicaemia) or joints and lead to serious infection.
- All these problems can be prevented by early treatment.

Can you catch gonorrhoea again?

DRAFT

- Yes you can.
- To prevent this ensure your partners have been treated before having sex with them again.
- Protect your self with new partners by ensuring a condom is used for all vaginal/ anal/ oral contact.

Or

- Ensure that both you and a new partner have a sexual health screen **before** any unprotected sex.

Gonorrhoea in pregnancy

- Gonorrhoea can occur in pregnant women and it is important that it is treated properly to prevent infection in the baby.
- The tests and treatment are similar to that outlined above – your doctor will discuss things in more detail with you.

Summary

This report updates U.S. Public Health Service recommendations for the management of health-care personnel (HCP) who have occupational exposure to blood and other body fluids that might contain human immunodeficiency virus (HIV). Although the principles of exposure management remain unchanged, recommended HIV postexposure prophylaxis (PEP) regimens have been changed. This report emphasizes adherence to HIV PEP when it is indicated for an exposure, expert consultation in management of exposures, follow-up of exposed workers to improve adherence to PEP, and monitoring for adverse events, including seroconversion. To ensure timely postexposure management and administration of HIV PEP, clinicians should consider occupational exposures as urgent medical concerns.

Introduction

Although preventing exposures to blood and body fluids is the primary means of preventing occupationally acquired human immunodeficiency virus (HIV) infection, appropriate postexposure management is an important element of workplace safety. In 1996, the first U.S. Public Health Service (PHS) recommendations for the use of postexposure prophylaxis (PEP) after occupational exposure to HIV were published; these recommendations have been updated twice (*1*–*3*). Since publication of the most recent guidelines in 2001, new antiretroviral agents have been approved by the Food and Drug Administration (FDA), and additional information has become available regarding the use and safety of HIV PEP. In August 2003, CDC convened a meeting of a PHS interagency working group* and consultants to assess use of HIV PEP. On the basis of this discussion, the PHS working group decided that updated recommendations for the management of occupational exposure to HIV were warranted.

This report modifies and expands the list of antiretroviral medications that can be considered for use as PEP. This report also emphasizes prompt management of occupational exposures, selection of tolerable regimens, attention to potential drug interactions involving drugs that could be included in HIV PEP regimens and other medications, consultation with experts for postexposure management strategies (especially determining whether an exposure has actually occurred) and selection of HIV PEP regimens, use of HIV rapid testing, and counseling and follow-up of exposed personnel.

Recommendations on the management of occupational exposures to hepatitis B virus or hepatitis C virus have been published previously (*3*) and are not included in this report. Recommendations for nonoccupational (e.g., sexual, pediatric, and perinatal) HIV exposures also have been published previously (*4*–*6*).

* This interagency working group included representatives from CDC, FDA, the Health Resources and Services Administration, and the National Institutes of Health. Information included in these recommendations might not represent FDA approval or approved labeling for the particular product or indications in question. Specifically, the terms "safe" and "effective" might not be synonymous with the FDA-defined legal standard for product approval.

The material in this report originated in the National Center for Infectious Diseases, Anne Schuchat, MD, Acting Director; Division of Healthcare Quality Promotion, Denise M. Cardo, MD, Director.

Definition of Health-Care Personnel and Exposure

The definitions of health-care personnel (HCP) and occupational exposures are unchanged from those used in 2001 (*3*). The term HCP refers to all paid and unpaid persons working in health-care settings who have the potential for exposure to infectious materials (e.g., blood, tissue, and specific body fluids and medical supplies, equipment, or environmental

surfaces contaminated with these substances). HCP might include, but are not limited to, emergency medical service personnel, dental personnel, laboratory personnel, autopsy personnel, nurses, nursing assistants, physicians, technicians, therapists, pharmacists, students and trainees, contractual staff not employed by the health-care facility, and persons not directly involved in patient care but potentially exposed to blood and body fluids (e.g., clerical, dietary, housekeeping, maintenance, and volunteer personnel). The same principles of exposure management could be applied to other workers who have potential for occupational exposure to blood and body fluids in other settings.

An exposure that might place HCP at risk for HIV infection is defined as a percutaneous injury (e.g., a needlestick or cut with a sharp object) or contact of mucous membrane or nonintact skin (e.g., exposed skin that is chapped, abraded, or afflicted with dermatitis) with blood, tissue, or other body fluids that are potentially infectious. In addition to blood and visibly bloody body fluids, semen and vaginal secretions also are considered potentially infectious. Although semen and vaginal secretions have been implicated in the sexual transmission of HIV, they have not been implicated in occupational transmission from patients to HCP. The following fluids also are considered potentially infectious: cerebrospinal fluid, synovial fluid, pleural fluid, peritoneal fluid, pericardial fluid, and amniotic fluid. The risk for transmission of HIV infection from these fluids is unknown; the potential risk to HCP from occupational exposures has not been assessed by epidemiologic studies in health-care settings. Feces, nasal secretions, saliva, sputum, sweat, tears, urine, and vomitus are not considered potentially infectious unless they are visibly bloody; the risk for transmission of HIV infection from these fluids and materials is low (*7*).

Any direct contact (i.e., contact without barrier protection) to concentrated virus in a research laboratory or production facility requires clinical evaluation. For human bites, clinical evaluation must include the possibility that both the person bitten and the person who inflicted the bite were exposed to bloodborne pathogens. Transmission of HIV infection by this route has been reported rarely, but not after an occupational exposure (*8–12*).

Risk for Occupational Transmission of HIV

The risks for occupational transmission of HIV have been described; risks vary with the type and severity of exposure (*2,3,7*). In prospective studies of HCP, the average risk for HIV transmission after a percutaneous exposure to HIV-infected blood has been estimated to be approximately 0.3% (95% confidence interval [CI] = 0.2%–0.5%) (*7*) and after a mucous membrane exposure, approximately 0.09% (CI = 0.006%–0.5%) (*3*). Although episodes of HIV transmission after nonintact skin exposure have been documented, the average risk for transmission by this route has not been precisely quantified but is estimated to be less than the risk for mucous membrane exposures. The risk for transmission after exposure to fluids or tissues other than HIV-infected blood also has not been quantified but is probably considerably lower than for blood exposures.

Epidemiologic and laboratory studies suggest that multiple factors might affect the risk for HIV transmission after an occupational exposure (*3*). In a retrospective case-control study of HCP who had percutaneous exposure to HIV, increased risk for HIV infection was associated with exposure to a larger quantity of blood from the source person as indicated by 1) a device (e.g., a needle) visibly contaminated with the patient's blood, 2) a procedure that involved a needle being placed directly in a vein or artery, or 3) a deep injury. The risk also was increased for exposure to blood from source persons with terminal illness, possibly reflecting either the higher titer of HIV in blood late in the course of acquired immunodeficiency syndrome (AIDS) or other factors (e.g., the presence of syncytia-inducing strains of HIV). A laboratory study that demonstrated that more blood is transferred by deeper injuries and hollow-bore needles lends further support for the observed variation in risk related to blood quantity (*3*).

The use of source-person viral load as a surrogate measure of viral titer for assessing transmission risk has not yet been established. Plasma viral load (e.g., HIV RNA) reflects only the level of cell-free virus in the peripheral blood; latently infected cells might transmit infection in the absence of viremia. Although a lower viral load (e.g., <1,500 RNA copies/mL) or one that is below the limits of detection probably indicates a lower titer exposure, it does not rule out the possibility of transmission.

Antiretroviral Agents for PEP

Antiretroviral agents from five classes of drugs are currently available to treat HIV infection (*13,14*). These include the nucleoside reverse transcriptase inhibitors (NRTIs), nucleotide reverse transcriptase inhibitors (NtRTIs), nonnucleoside reverse transcriptase inhibitors (NNRTIs), protease inhibitors (PIs), and a single fusion inhibitor. Only antiretroviral agents approved by FDA for treatment of HIV infection are included in these guidelines. The recommendations in this report provide guidance for two- or-more drug PEP regimens on the basis of the level of risk for HIV transmission represented by the exposure (Tables 1 and 2; Appendix).

TABLE 1. Recommended HIV postexposure prophylaxis (PEP) for percutaneous injuries

Exposure type	Infection status of source				
	HIV-positive, class 1*	HIV-positive, class 2*	Source of unknown HIV status†	Unknown source§	HIV-negative
Less severe¶	Recommend basic 2-drug PEP	Recommend expanded ≥3-drug PEP	Generally, no PEP warranted; however, consider basic 2-drug PEP** for source with HIV risk factors††	Generally, no PEP warranted; however, consider basic 2-drug PEP** in settings in which exposure to HIV-infected persons is likely	No PEP warranted
More severe§§	Recommend expanded 3-drug PEP	Recommend expanded ≥3-drug PEP	Generally, no PEP warranted; however, consider basic 2-drug PEP** for source with HIV risk factors††	Generally, no PEP warranted; however, consider basic 2-drug PEP** in settings in which exposure to HIV-infected persons is likely	No PEP warranted

* HIV-positive, class 1 — asymptomatic HIV infection or known low viral load (e.g., <1,500 ribonucleic acid copies/mL). HIV-positive, class 2 — symptomatic HIV infection, acquired immunodeficiency syndrome, acute seroconversion, or known high viral load. If drug resistance is a concern, obtain expert consultation. Initiation of PEP should not be delayed pending expert consultation, and, because expert consultation alone cannot substitute for face-to-face counseling, resources should be available to provide immediate evaluation and follow-up care for all exposures.

† For example, deceased source person with no samples available for HIV testing.

§ For example, a needle from a sharps disposal container.

¶ For example, solid needle or superficial injury.

** The recommendation "consider PEP" indicates that PEP is optional; a decision to initiate PEP should be based on a discussion between the exposed person and the treating clinician regarding the risks versus benefits of PEP.

†† If PEP is offered and administered and the source is later determined to be HIV-negative, PEP should be discontinued.

§§ For example, large-bore hollow needle, deep puncture, visible blood on device, or needle used in patient's artery or vein.

TABLE 2. Recommended HIV postexposure prophylaxis (PEP) for mucous membrane exposures and nonintact skin* exposures

Exposure type	Infection status of source				
	HIV-positive, class 1†	HIV-positive, class 2†	Source of unknown HIV status§	Unknown source¶	HIV-negative
Small volume**	Consider basic 2-drug PEP††	Recommend basic 2-drug PEP	Generally, no PEP warranted§§	Generally, no PEP warranted	No PEP warranted
Large volume¶¶	Recommend basic 2-drug PEP	Recommend expanded ≥3-drug PEP	Generally, no PEP warranted; however, consider basic 2-drug PEP†† for source with HIV risk factors§§	Generally, no PEP warranted; however, consider basic 2-drug PEP†† in settings in which exposure to HIV-infected persons is likely	No PEP warranted

* For skin exposures, follow-up is indicated only if evidence exists of compromised skin integrity (e.g., dermatitis, abrasion, or open wound).

† HIV-positive, class 1 — asymptomatic HIV infection or known low viral load (e.g., <1,500 ribonucleic acid copies/mL). HIV-positive, class 2 — symptomatic HIV infection, AIDS, acute seroconversion, or known high viral load. If drug resistance is a concern, obtain expert consultation. Initiation of PEP should not be delayed pending expert consultation, and, because expert consultation alone cannot substitute for face-to-face counseling, resources should be available to provide immediate evaluation and follow-up care for all exposures.

§ For example, deceased source person with no samples available for HIV testing.

¶ For example, splash from inappropriately disposed blood.

** For example, a few drops.

†† The recommendation "consider PEP" indicates that PEP is optional; a decision to initiate PEP should be based on a discussion between the exposed person and the treating clinician regarding the risks versus benefits of PEP.

§§ If PEP is offered and administered and the source is later determined to be HIV-negative, PEP should be discontinued.

¶¶ For example, a major blood splash.

Toxicity and Drug Interactions of Antiretroviral Agents

Persons receiving PEP should complete a full 4-week regimen (*3*). However, as a result of toxicity and side effects among HCP, a substantial proportion of HCP have been unable to complete a full 4-week course of HIV PEP (*15–20*). Because all antiretroviral agents have been associated with side effects (Table 3), the toxicity profile of these agents, including the frequency, severity, duration, and reversibility of side effects, is an important consideration in selection of an HIV PEP regimen. The majority of data concerning adverse events have been reported primarily for persons with established HIV infection receiving prolonged antiretroviral therapy and therefore might not reflect the experience of uninfected persons who take PEP. Anecdotal evidence from clinicians knowledgeable about HIV treatment indicates that antiretroviral agents are tolerated more poorly among HCP taking HIV PEP than among HIV-infected patients on antiretroviral medications.

TABLE 3. Primary side effects and toxicities associated with antiretroviral agents used for HIV postexposure prophylaxis, by class and agent

Class and agent	Side effect and toxicity
Nucleoside reverse transcriptase inhibitors (NRTI)	**Class warning: all NRTIs have the potential to cause lactic acidosis with hepatic steatosis**
Zidovudine (Retrovir®; ZDV, AZT)	Anemia, neutropenia, nausea, headache, insomnia, muscle pain, and weakness
Lamivudine (Epivir®, 3TC)	Abdominal pain, nausea, diarrhea, rash, and pancreatitis
Stavudine (Zerit™; d4T)	Peripheral neuropathy, headache, diarrhea, nausea, insomnia, anorexia, pancreatitis, elevated liver function tests (LFTs), anemia, and neutropenia
Didanosine (Videx®; ddI)	Pancreatitis, lactic acidosis, neuropathy, diarrhea, abdominal pain, and nausea
Emtricitabine (Emtriva, FTC)	Headache, nausea, vomiting, diarrhea, and rash. Skin discoloration (mild hyperpigmentation on palms and soles), primarily among nonwhites
Nucleotide analogue reverse transcriptase inhibitor (NtRTI)	**Class warning: All NtRTIs have the potential to cause lactic acidosis with hepatic steatosis**
Tenofovir (Viread®; TDF)	Nausea, diarrhea, vomiting, flatulence, and headache
Nonnucleoside reverse transcriptase inhibitors (NNRTIs)	
Efavirenz (Sustiva®; EFV)	Rash (including cases of Stevens-Johnson syndrome), insomnia, somnolence, dizziness, trouble concentrating, abnormal dreaming, and teratogenicity
Protease inhibitor	
Indinavir (Crixivan®; IDV)	Nausea, abdominal pain, nephrolithiasis, and indirect hyperbilirubinemia
Nelfinavir (Viracept®; NFV)	Diarrhea, nausea, abdominal pain, weakness, and rash
Ritonavir (Norvir®; RTV)	Weakness, diarrhea, nausea, circumoral paresthesia, taste alteration, and elevated cholesterol and triglycerides
Saquinavir (Invirase®; SQV)	Diarrhea, abdominal pain, nausea, hyperglycemia, and elevated LFTs
Fosamprenavir (Lexiva®, FOSAPV)	Nausea, diarrhea, rash, circumoral paresthesia, taste alteration, and depression
Atazanavir (Reyataz®; ATV)	Nausea, headache, rash, abdominal pain, diarrhea, vomiting, and indirect hyperbilirubinemia
Lopinavir/ritonavir (Kaletra®; LPV/RTV)	Diarrhea, fatigue, headache, nausea, and increased cholesterol and triglycerides
Fusion inhibitor	
Enfuvirtide (Fuzeon®; T-20)	Local injection site reactions, bacterial pneumonia, insomnia, depression, peripheral neuropathy, and cough

Sources: Package inserts; Panel on Clinical Practices for Treatment of HIV Infection. Guidelines for the use of antiretroviral agents in HIV-infected adults and adolescents—April 7, 2005. Washington, DC: National Institutes of Health; 2005. Available at http://aidsinfo.nih.gov/guidelines/default_db2.asp?id=50.

Side effects have been reported frequently by persons taking antiretroviral agents as PEP (*15–23*). In multiple instances, a substantial (range: 17%–47%) proportion of HCP taking PEP after occupational exposures to HIV-positive sources did not complete a full 4-week course of therapy because of inability to tolerate the drugs (*15–17,19,20*). Data from the National Surveillance System for Health Care Workers (NaSH), CDC's occupational surveillance system for occupational exposures and infections in hospitals, for June 1995–December 2004 indicate that 401 (46.9%) of 921 HCP with at least one follow-up visit after starting PEP experienced one or more symptoms. The symptom reported most frequently was nausea (26.5%), followed by malaise and fatigue (22.8%) (CDC, unpublished data, 2005). Of 503 HCP who stopped HIV PEP prematurely (<28 days), 361 (24.0%) did so because of adverse effects of the drugs. Similar data have been reported from the Italian Registry of Antiretroviral Postexposure Prophylaxis, which includes data primarily on HCP taking PEP but also collects data on those taking PEP after nonoccupational exposures (*18*). In multivariate analysis, those taking regimens that include PI were more likely to experience PEP-associated side effects and to discontinue PEP prematurely (<28 days). Because side effects are frequent and

particularly because they are cited as a major reason for not completing PEP regimens as prescribed, the selection of regimens should be heavily influenced toward those that are tolerable for short-term use.

In addition, all approved antiretroviral agents might have potentially serious drug interactions when used with certain other drugs, requiring careful evaluation of concomitant medications, including over-the-counter medications and supplements (e.g., herbals), used by an exposed person before prescribing PEP and close monitoring for toxicity of anyone receiving these drugs (*24–33*) (Tables 3–5). PIs and NNRTIs have the greatest potential for interactions with other drugs. Information regarding potential drug interactions has been published (*13,24–33*). Additional information is included in the manufacturers' package inserts. Because of interactions, certain drugs should not be administered concomitantly with PIs or with efavirenz (EFV) (Tables 4 and 5). Consultation with a pharmacist might be considered.

Selection of HIV PEP Regimens

Determining which agents and how many to use or when to alter a PEP regimen is primarily empiric (*34*). Guidelines for treating HIV infection, a condition typically involving a high total body burden of HIV, recommend use of three or more drugs (*13,14*); however, the applicability of these recommendations to PEP is unknown. Among HIV-infected patients, combination regimens with three or more antiretroviral agents have proved superior to monotherapy and dual-therapy regimens in reducing HIV viral load, reducing incidence of opportunistic infections and death, and delaying onset of drug resistance (*13,14*). In theory, a combination of drugs with activity at different stages in the viral replication cycle (e.g., nucleoside analogues with a PI) might offer an additive preventive effect in PEP, particularly for occupational exposures that pose an increased risk for transmission or for transmission of a resistant virus. Although use of a three- (or more) drug regimen might be justified for exposures that pose an increased risk for transmission, whether the potential added toxicity of a third or fourth drug is justified for lower-risk exposures is uncertain, especially in the absence of data supporting increased efficacy of more drugs in the context of occupational PEP. Offering a two-drug regimen is a viable option, primarily because the benefit of completing a full course of this regimen exceeds the benefit of adding the third agent and risking noncompletion (*35*). In addition, the total body burden of HIV is substantially lower among exposed HCP than among persons with established HIV infection. For these reasons, the recommendations in this report provide guidance for two- and three- (or more) drug PEP regimens on the basis of the level of risk for HIV transmission represented by the exposure (Tables 1 and 2; Appendix).

Resistance to Antiretroviral Agents

Known or suspected resistance of the source virus to antiretroviral agents, particularly those that might be included in a PEP regimen, is a concern for persons making decisions about PEP (*36*). Drug resistance to all available antiretroviral agents has been reported, and cross-resistance within drug classes is frequent (*37*). Although occupational transmission of drug-resistant HIV strains has been reported despite PEP

TABLE 4. Prescription and over-the-counter drugs that should not be administered with protease inhibitors (PIs) because of drug interactions*

Drug	Comment
Antimycobacterials: rifampin	Decreases plasma concentrations and area under plasma concentration curve of the majority of PIs by approximately 90%, which might result in loss of therapeutic effect and development of resistance
Benzodiazepines: midazolam, triazolam	Contraindicated because of potential for serious or life-threatening events (e.g., prolonged or increased sedation or respiratory depression)
Ergot derivatives: dihydroergotamine, ergotamine, ergonovine, methylergonovine	Contraindicated because of potential for serious or life-threatening events (e.g., acute ergot toxicity characterized by peripheral vasospasm and ischemia of the extremities and other tissues)
Gastrointestinal motility agent: cisapride	Contraindicated because of potential for serious or life-threatening events (e.g., cardiac arrhythmias)
HMG-CoA reductase inhibitors ("statins"): lovastatin, simvastatin	Potential for serious reactions (e.g., myopathy, including rhabdomyolysis); atorvastatin may be used cautiously, beginning with lowest possible starting dose, and monitoring for adverse events
Neuroleptic: pimozide	Contraindicated because of potential for serious or life-threatening events (e.g., cardiac arrhythmias)
Inhaled steroids: fluticasone	Coadministration of fluticasone and ritonavir-boosted protease inhibitors are not recommended unless the potential benefit to the patient outweighs the risk for systemic corticosteroid side effect
Herbal products:	Coadministration might reduce plasma concentrations of protease inhibitors, which might result in loss of therapeutic effect and development of resistance
St. John's wort (hypericum perforatum), garlic	Garlic might lower saquinavir level

* This table does not list all products that should not be administered with PIs (atazanavir, lopinavir/ritonavir, fosamprenavir, indinavir, nelfinavir, saquinavir). Product labels should be consulted for additional information regarding drug interactions.

with combination drug regimens (*36,38–40*), the effect of exposure to a resistant virus on transmission and transmissibility is not well understood.

Since publication of the previous guidelines, an additional report of an occupational HIV seroconversion despite combination HIV PEP has been published (Table 6) (*38*), bringing the total number of reports worldwide to six. The exposure was a percutaneous injury sustained by a nurse performing a phlebotomy on a heavily treatment-experienced patient. At the time of the exposure, the source patient was failing treatment with stavudine (d4T), lamivudine (3TC), ritonavir (RTV), and saquinavir (SQV) and had a history of previous treatment with zidovudine (ZDV) and zalcitabine (ddC). Genotypic resistance testing performed within 1 month of the exposure suggested resistance to ZDV and 3TC. Phenotypic testing confirmed resistance to 3TC but demonstrated relative susceptibility to ZDV and d4T. The source virus demonstrated no evidence of resistance to nevirapine (NVP) or other NNRTIs. The initial HIV PEP regimen started within 95 minutes of the exposure was ZDV, 3TC, and indinavir.

TABLE 6. Reported instances of failure of combination drug postexposure prophylaxis (PEP) to prevent HIV-infection among health-care personnel exposed to HIV-infected blood through percutaneous injury

Year of incident	Device	PEP regimen*	Time to first dose (hrs)	No. of days to onset of retroviral illness	No. of days to document seroconversion†	Source-patient		
						HIV-infection status	On anti retrovirals	Virus resistant to antiretrovirals§
1992¶	Biopsy needle	ZDV, ddI	0.5	23	23	AIDS, terminally ill	Yes	Unknown

¶¶¶ ZDV, 3TC, and IDV initially and then changed after first dose to d4T, ddI, and NVP; then ddI discontinued after 8 days; and d4T and NVP taken for 4 weeks.

The worker was referred to a hospital where the regimen was changed within 6 hours of the exposure to didanosine (ddI), d4T, and NVP because of concerns regarding possible drug resistance to certain or all of the components of the initial PEP regimen. The exposed worker stopped ddI after 8 days because of symptoms but continued to take d4T and NVP, stopping at day 24 because of a generalized macular pruritic rash and mild thrombocytopenia. Seroconversion was documented at 3 months. Sequencing of viruses from the source and exposed worker demonstrated their close relatedness. Virus from the worker demonstrated the same resistance patterns as those in the source patient. In addition, the worker's virus had a mutation suggesting resistance to the NNRTI class (*38*).

Empiric decisions regarding the presence of antiretroviral drug resistance are often difficult because patients frequently take more than one antiretroviral agent. Resistance should be suspected in a source patient when clinical progression of disease or a persistently increasing viral load or decline in CD4+ T-cell count occurs despite therapy, or when no virologic response to therapy occurs. However, resistance testing of the source virus at the time of an exposure is impractical because the results will not be available in time to influence the choice of the initial PEP regimen. No data suggest that modification of a PEP regimen after resistance testing results become available (usually 1–2 weeks) improves efficacy of PEP (*41*).

Antiretroviral Drugs During Pregnancy

Data regarding the potential effects of antiretroviral drugs on the developing fetus or neonate are limited (*3*). Carcinogenicity and mutagenicity are evident in certain in vitro screening tests for ZDV and all other FDA-licensed NRTIs. The relevance of animal data to humans is unknown; however, because teratogenic effects were reported among primates at drug exposures similar to those representing human therapeutic exposure, pregnant women should not use efavirenz (EFV). Indinavir (IDV) is associated with infrequent side effects in adults (i.e., hyperbilirubinemia and renal stones) that could be problematic for a newborn. Because the half-life of IDV in adults is short, these concerns might be relevant only if the drug is administered shortly before delivery. Other concerns regarding use of PEP during pregnancy have been raised by reports of mitochondrial dysfunction leading to neurologic disease and death among uninfected children whose mothers had taken antiretroviral drugs to prevent perinatal HIV transmission and of fatal and nonfatal lactic acidosis in pregnant women treated throughout gestation with a combination of d4T and ddI (*3*).

Management of Occupational Exposure by Emergency Physicians

Although PHS guidelines for the management of occupational exposures to HIV were first published in 1985 (*42*), HCP often are not familiar with these guidelines. Focus groups conducted among emergency department (ED) physicians in 2002 indicated that of 71 participants, >95% had not read the 2001 guidelines before being invited to participate (*43*). All physicians participating in these focus groups had managed occupational exposures to blood or body fluids. They cited three challenges in exposure management most frequently: evaluation of an unknown source patient or a source patient who refused testing, inexperience in managing occupational HIV exposures, and counseling of exposed workers in busy EDs.

Occupational HIV Exposure Management and PEP Use in U.S. Hospitals

Analysis of NaSH data for June 1995–December 2004 provides information regarding the management of occupational exposure to HIV in a convenience sample of 95 U.S. hospitals. These data indicate improved adherence to PHS recommendations concerning use of HIV PEP after occupational exposures. A total of 28,010 exposures to blood and body fluids were reported by these hospitals (CDC, unpublished data, 2005). For all 25,510 exposures with known sources, 1,350 (5.3%) were to HIV-positive sources, 15,301 (60.0%) to HIV-negative sources, and 8,859 (34.7%) to sources of unknown HIV status. Of 1,350 HCP exposed to a known HIV-positive source, 788 (58.4%) started PEP, and 317 (49%) of 647 for whom follow-up information was available took PEP for ≥21 days. The overall median duration of HIV PEP after exposure to an HIV-positive source was 27 days, increasing from 10 days in 1995 to 26.5 days in 2004; the overall median duration of HIV PEP after exposure to an HIV-negative source was 2 days, decreasing from 7.5 days in 1995 to 1 day in 2004. The use of rapid HIV tests for evaluation of source patients has increased; during 1995–1997, none of 25 NaSH facilities used rapid HIV tests, whereas in 2004, a total of 21 (84%) did (CDC, unpublished data, 2005). Rapid HIV tests could result in decreased use of PEP and spare personnel both undue anxiety and adverse effects of antiretroviral PEP (*44–47*). The annual median time to initiation of PEP was consistent (2 hours). Of 1,350 HCP with exposures to HIV-positive sources, 909 (67.1%) had at least one follow-up serologic test recorded, but only 289 (31.8%) had tests recorded at 4–6 months (CDC, unpublished data, 2005).

In 1996, of 24 HCP taking PEP after exposure to HIV-positive sources, 10 (42%) took a three-drug PEP regimen compared with 30 (76.9%) of 39 in 2004 (CDC, unpublished data, 2005). After 227 HIV exposures for which only a two-drug PEP regimen was recommended (i.e., the exposure was to mucous membranes or skin or was a superficial percutaneous injury and the source person did not have end-stage AIDS or acute HIV illness), 104 (45.8%) HCP initiated a three-drug HIV PEP regimen. The National Clinicians' Post-Exposure Prophylaxis Hotline (PEPline)† reports similar findings. PEPline staff recommended changing or discontinuing PEP regimens for 45 (38%) of 118 exposures involving source patients with known viral load or CD4 cell count concerning which they were consulted during April 2002–March 2003 (*48*; R. Goldschmidt, PEPline, personal communication, 2004). For 14 (11.9%) HCP, the recommendation was to decrease the number of drugs in the PEP regimens; for 22 (18.7%) HCP, the recommendation was to increase the number of drugs; and for nine (7.6%), the recommendation was to change the PEP regimen, keeping the same number of drugs.

Recommendations for the Management of HCP Potentially Exposed to HIV

Exposure prevention remains the primary strategy for reducing occupational bloodborne pathogen infections. However, occupational exposures will continue to occur, and PEP will remain an important element of exposure management.

HIV PEP

The recommendations provided in this report (Tables 1 and 2; Appendix) apply to situations in which HCP have been exposed to a source person who either has or is considered likely to have HIV infection. These recommendations are based on the risk for HIV infection after different types of exposure and on limited data regarding efficacy and toxicity of PEP. If PEP is offered and taken and the source is later determined to be HIV-negative, PEP should be discontinued. Although concerns have been expressed regarding HIV-negative sources being in the window period for seroconversion, no case of transmission involving an exposure source during the window period has been reported in the United States (*39*). Rapid HIV testing of source patients can facilitate making timely decisions regarding use of HIV PEP after occupational exposures to sources of unknown HIV status. Because the majority of occupational HIV exposures do not result in transmission of HIV, potential toxicity must be considered when prescribing PEP. Because of the complexity of selecting HIV PEP regimens, when possible, these recommendations should be implemented in consultation with persons having expertise in antiretroviral therapy and HIV transmission. Reevaluation of exposed HCP should be strongly encouraged within 72 hours postexposure, especially as additional information about the exposure or source person becomes available.

Timing and Duration of PEP

PEP should be initiated as soon as possible, preferably within hours rather than days of exposure. If a question exists concerning which antiretroviral drugs to use, or whether to use a basic or expanded regimen, the basic regimen should be started immediately rather than delay PEP administration. The optimal duration of PEP is unknown. Because 4 weeks of ZDV appeared protective in occupational and animal studies, PEP should be administered for 4 weeks, if tolerated (*49–52*).

Recommendations for the Selection of Drugs for HIV PEP

The selection of a drug regimen for HIV PEP must balance the risk for infection against the potential toxicities of the agent(s) used. Because PEP is potentially toxic, its use is not justified for exposures that pose a negligible risk for transmission (Tables 1 and 2). The initial HIV PEP regimens recommended in these guidelines should be viewed as suggestions that can be changed if additional information is obtained concerning the source of the occupational exposure (e.g., possible treatment history or antiretroviral drug resistance) or if expert consultation is provided. Given the complexity of choosing and administering HIV PEP, whenever possible, consultation with an infectious diseases consultant or another physician who has experience with antiretroviral agents is recommended, but it should not delay timely initiation of PEP.

Consideration should be given to the comparative risk represented by the exposure and information regarding the exposure source, including history of and response to antiretroviral therapy based on clinical response, CD4+ T-cell counts, viral load measurements, and current disease stage. When the source person's virus is known or suspected to be resistant to one or more of the drugs considered for the PEP regimen, the selection of drugs to which the source person's virus is unlikely to be resistant is recommended; expert consultation is advised. If this information is not immediately available, initiation of PEP, if indicated, should not be delayed; changes

† Administered by staff members from the University of California at San Francisco and San Francisco General Hospital; supported by the Health Resources and Services Administration Ryan White CARE Act and AIDS Education and Training Centers, and by CDC.

in the regimen can be made after PEP has started, as appropriate. For HCP who initiate PEP, re-evaluation of the exposed person should occur within 72 hours postexposure, especially if additional information about the exposure or source person becomes available.

PHS continues to recommend stratification of HIV PEP regimens based on the severity of exposure and other considerations (e.g., concern for antiretroviral drug resistance in the exposure source). The majority of HIV exposures will warrant a two-drug regimen, using two NRTIs or one NRTI and one NtRTI (Tables 1 and 2; Appendix). Combinations that can be considered for PEP include ZDV and 3TC or emtricitabine (FTC); d4T and 3TC or FTC; and tenofovir (TDF) and 3TC or FTC. In the previous PHS guidelines, a combination of d4T and ddI was considered one of the first-choice PEP regimens; however, this regimen is no longer recommended because of concerns about toxicity (especially neuropathy and pancreatitis) and the availability of more tolerable alternative regimens (*3*).

The addition of a third (or even a fourth) drug should be considered for exposures that pose an increased risk for transmission or that involve a source in whom antiretroviral drug resistance is likely. The addition of a third drug for PEP after a high-risk exposure is based on demonstrated effectiveness in reducing viral burden in HIV-infected persons. However, no definitive data exist that demonstrate increased efficacy of three- compared with two-drug HIV PEP regimens. Previously, IDV, nelfinavir (NFV), EFV, or abacavir (ABC) were recommended as first-choice agents for inclusion in an expanded PEP regimen (*3*).

PHS now recommends that expanded PEP regimens be PI-based. The PI preferred for use in expanded PEP regimens is lopinavir/ritonavir (LPV/RTV). Other PIs acceptable for use in expanded PEP regimens include atazanavir, fosamprenavir, RTV-boosted IDV, RTV-boosted SQV, or NFV (Appendix). Although side effects are common with NNRTIs, EFV may be considered for expanded PEP regimens, especially when resistance to PIs in the source person's virus is known or suspected. Caution is advised when EFV is used in women of childbearing age because of the risk of teratogenicity.

Drugs that may be considered as alternatives to the expanded regimens, with warnings about side effects and other adverse events, are EFV or PIs as noted in the Appendix in combination with ddI and either 3TC or FTC. The fusion inhibitor enfuvirtide (T20) has theoretic benefits for use in PEP because its activity occurs before viral-host cell integration; however, it is not recommended for routine HIV PEP because of the mode of administration (subcutaneous injection twice daily). Furthermore, use of T20 has the potential for production of anti-T20 antibodies that cross react with HIV gp41. This could result in a false-positive, enzyme immunoassay (EIA) HIV antibody test among HIV-uninfected patients. A confirmatory Western blot test would be expected to be negative in such cases. T20 should only be used with expert consultation.

Antiviral drugs not recommended for use as PEP, primarily because of the higher risk for potentially serious or life-threatening adverse events, include ABC, delavirdine, ddC, and, as noted previously, the combination of ddI and d4T. NVP should not be included in PEP regimens except with expert consultation because of serious reported side effects, including hepatotoxicty (with one instance of fulminant liver failure requiring liver transplantation), rhabdomyolysis, and hypersensitivity syndrome (*53–55*).

Because of the complexity of selection of HIV PEP regimens, consultation with persons having expertise in antiretroviral therapy and HIV transmission is strongly recommended. Certain institutions have required consultation with a hospital epidemiologist or infectious diseases consultant when HIV PEP use is under consideration. This can be especially important in management of a pregnant or breastfeeding worker or a worker who has been exposed to a heavily treatment-experienced source (Box 1).

- HIV/AIDS Treatment Information Service at http://aidsinfo.nih.gov.

Follow-Up of Exposed HCP

Postexposure Testing

HCP with occupational exposure to HIV should receive follow-up counseling, postexposure testing, and medical evaluation regardless of whether they receive PEP. HIV-antibody

BOX 1. Situations for which expert consultation* for HIV postexposure prophylaxis (PEP) is advised

- Delayed (i.e., later than 24–36 hours) exposure report
  - — Interval after which lack of benefit from PEP undefined
- Unknown source (e.g., needle in sharps disposal container or laundry)
  - — Use of PEP to be decided on a case-by-case basis
  - — Consider severity of exposure and epidemiologic likelihood of HIV exposure
  - — Do not test needles or other sharp instruments for HIV
- Known or suspected pregnancy in the exposed person
  - — Use of optimal PEP regimens not precluded
  - — PEP not denied solely on basis of pregnancy
- Breastfeeding in the exposed person
  - — Use of optimal PEP regimens not precluded
  - — PEP not denied solely on basis of breastfeeding
- Resistance of the source virus to antiretroviral agents
  - — Influence of drug resistance on transmission risk unknown
  - — If source person's virus is known or suspected to be resistant to one or more of the drugs considered for PEP, selection of drugs to which the source person's virus is unlikely to be resistant recommended
  - — Resistance testing of the source person's virus at the time of the exposure not recommended
  - — Initiation of PEP not to be delayed while awaiting any results of resistance testing
- Toxicity of the initial PEP regimen
  - — Adverse symptoms (e.g., nausea and diarrhea) common with PEP
  - — Symptoms often manageable without changing PEP regimen by prescribing antimotility or antiemetic agents
  - — In other situations, modifying the dose interval (i.e., taking drugs after meals or administering a lower dose of drug more frequently throughout the day, as recommended by the manufacturer) might help alleviate symptoms when they occur

* Either with local experts or by contacting the National Clinicians' Post-Exposure Prophylaxis Hotline (PEPline), telephone 888-448-4911.

testing by enzyme immunoassay should be used to monitor HCP for seroconversion for >6 months after occupational HIV exposure. After baseline testing at the time of exposure, follow-up testing could be performed at 6 weeks, 12 weeks, and 6 months after exposure. Extended HIV follow-up (e.g., for 12 months) is recommended for HCP who become infected with HCV after exposure to a source coinfected with HIV and HCV. Whether extended follow-up is indicated in other circumstances (e.g., exposure to a source co-infected with HIV and HCV in the absence of HCV seroconversion or for exposed persons with a medical history suggesting an impaired ability to mount an antibody response to acute infection) is unclear. Although rare instances of delayed HIV seroconversion have been reported (*56,57*), the infrequency of this occurrence does not warrant adding to exposed persons' anxiety by routinely extending the duration of postexposure follow-up. However, this should not preclude a decision to extend follow-up in a particular situation based on the clinical judgment of the exposed person's health-care provider. The routine use of direct virus assays (e.g., HIV p24 antigen EIA or tests for HIV ribonucleic acid) to detect infection among exposed HCP usually is not recommended (*58*). Despite the ability of direct virus assays to detect HIV infection a few days earlier than EIA, the infrequency of occupational seroconversion and increased costs of these tests do not warrant their routine use in this setting. In addition, the relatively high rate of false-positive results of these tests in this setting could lead to unnecessary anxiety or treatment (*59,60*). Nevertheless, HIV testing should be performed on any exposed person who has an illness compatible with an acute retroviral syndrome, regardless of the interval since exposure. A person in whom HIV infection is identified should be referred for medical management to a specialist with expertise in HIV treatment and counseling. Health-care providers caring for persons with occupationally acquired HIV infection can report these cases to CDC at telephone 800-893-0485 or to their state health departments.

Monitoring and Management of PEP Toxicity

If PEP is used, HCP should be monitored for drug toxicity by testing at baseline and again 2 weeks after starting PEP. The scope of testing should be based on medical conditions in the exposed person and the toxicity of drugs included in the PEP regimen. Minimally, laboratory monitoring for toxicity should include a complete blood count and renal and hepatic function tests. Monitoring for evidence of hyperglycemia should be included for HCP whose regimens include any PI; if the exposed person is receiving IDV, monitoring for crystalluria, hematuria, hemolytic anemia, and hepatitis also should be included. If toxicity is noted, modification of the regimen should be considered after expert consultation; further diagnostic studies might be indicated.

Exposed HCP who choose to take PEP should be advised of the importance of completing the prescribed regimen. Information should be provided about potential drug interactions and drugs that should not be taken with PEP, side effects of prescribed drugs, measures to minimize side effects, and methods of clinical monitoring for toxicity

during the follow-up period. HCP should be advised that evaluation of certain symptoms (e.g., rash, fever, back or abdominal pain, pain on urination or blood in the urine, or symptoms of hyperglycemia (e.g., increased thirst or frequent urination) should not be delayed.

HCP often fail to complete the recommended regimen often because they experience side effects (e.g., nausea or diarrhea). These symptoms often can be managed with antimotility and antiemetic agents or other medications that target specific symptoms without changing the regimen. In other situations, modifying the dose interval (i.e., administering a lower dose of drug more frequently throughout the day, as recommended by the manufacturer) might facilitate adherence to the regimen. Serious adverse events[§] should be reported to FDA's MedWatch program.

Although recommendations for follow-up testing, monitoring, and counseling of exposed HCP are unchanged from those published previously (*3*), greater emphasis is needed on improving follow-up care provided to exposed HCP (Box 2). This might result in increased adherence to HIV PEP regimens, better management of associated symptoms with ancillary medications or regimen changes, improved detection of serious adverse effects, and serologic testing among a larger proportion of exposed personnel to determine if infection is transmitted after occupational exposures. Closer follow-up should in turn reassure HCP who become anxious after these events (*61,62*). The psychologic impact on HCP of needlesticks or exposure to blood or body fluid should not be underestimated. Providing HCP with psychologic counseling should be an essential component of the management and care of exposed HCP.

Reevaluation and Updating of HIV PEP Guidelines

As new antiretroviral agents for treatment of HIV infection and additional information concerning early HIV infection and prevention of HIV transmission become available, the PHS Interagency Working Group will assess the need to update these guidelines. Updates will be published periodically as appropriate.

[§] Defined by FDA as follows: "Any adverse drug experience occurring at any dose that results in any of the following outcomes: death, a life-threatening adverse drug experience, inpatient hospitalization or prolongation of existing hospitalization, a persistent or significant disability/incapacity, or a congenital anomaly/birth defect. Important medical events that may not result in death, be life-threatening, or require hospitalization may be considered a serious adverse drug experience when, based upon appropriate medical judgment, they may jeopardize the patient or subject and may require medical or surgical intervention to prevent one of the outcomes listed in this definition" (*63*).

BOX 2. Follow-up of health-care personnel (HCP) exposed to known or suspected HIV-positive sources

- Exposed HCP should be advised to use precautions (e.g., avoid blood or tissue donations, breastfeeding, or pregnancy) to prevent secondary transmission, especially during the first 6–12 weeks postexposure.
- For exposures for which PEP is prescribed, HCP should be informed regarding
  - — possible drug toxicities and the need for monitoring,
  - — possible drug interactions, and
  - — the need for adherence to PEP regimens.
- Consider reevalution of exposed HCP 72 hours postexposure, especially after additional information about the exposure or source person becomes available.

Acknowledgments

APPENDIX

Basic and Expanded HIV Postexposure Prophylaxis Regimens

BASIC REGIMEN

- **Zidovudine (Retrovir™; ZDV; AZT) + lamivudine (Epivir®; 3TC); available as Combivir™**

Preferred dosing

- ZDV: 300 mg twice daily or 200 mg three times daily, with food; total: 600 mg daily
- 3TC: 300 mg once daily or 150 mg twice daily
- Combivir: one tablet twice daily

Dosage forms

- ZDV: 100 mg capsule, 300 mg tablet
- 3TC: 150 or 300 mg tablet
- Combivir: tablet, 300 mg ZDV + 150 mg 3TC

Advantages

- ZDV associated with decreased risk for HIV transmission
- ZDV used more often than other drugs for PEP for health-care personnel (HCP)
- Serious toxicity rare when used for PEP
- Side effects predictable and manageable with antimotility and antiemetic agents
- Can be used by pregnant HCP
- Can be given as a single tablet (COMBIVIR™) twice daily

Disadvantages

- Side effects (especially nausea and fatigue) common and might result in low adherence
- Source-patient virus resistance to this regimen possible
- Potential for delayed toxicity (oncogenic/teratogenic) unknown

- **Zidovudine (Retrovir®; ZDV; AZT) + emtrictabine (Emtriva™; FTC)**

Preferred dosing

- ZDV: 300 mg twice daily or 200 mg three times daily, with food; total: 600 mg/day, in 2–3 divided doses
- FTC: 200 mg (one capsule) once daily

Dosage forms
- ZDV: see above
- FTC: 200 mg capsule

FTC general comments
- Nucleoside analogue; same structure as 3TC, except fluoride residue at position 5 on pyrimidine ring
- Same resistance and safety profile as 3TC
- No apparent advantage over 3TC; tolerability and virologic response rates appear better than regimens containing ddI + d4T

Advantages
- ZDV: see above.
- FTC
  - Convenient (once daily)
  - Well tolerated
  - Long intracellular half-life (~40 hours)

Disadvantages
- ZDV: see above.
- FTC
  - Rash perhaps more frequent than with 3TC
  - No long-term experience with this drug
  - Cross resistance to 3TC
  - Hyperpigimentation among non-Caucasians with long-term use: 3%

- **Tenofovir DF (Viread®; TDF) + lamivudine (Epivir®; 3TC)**

Preferred dosing
- TDF: 300 mg once daily
- 3TC: 300 mg once daily or 150 mg twice daily

Dosage forms
- TDF: 300 mg tablet
- 3TC: see above

Advantages
- 3TC: see above
- TDF
  - Convenient dosing (single pill once daily)
  - Resistance profile activity against certain thymidine analogue mutations
  - Well tolerated

Disadvantages
- TDF
  - Same class warnings as nucleoside reverse transcriptase inhibitors (NRTIs)
  - Drug interactions
  - Increased TDF concentrations among persons taking atazanavir and lopinavir/ritonavir; need to monitor patients for TDF-associated toxicities
- Preferred dosage of atazanavir if used with TDF: 300 mg + ritonavir 100 mg once daily + TDF 300 mg once daily

- **Tenofovir DF (Viread®; TDF) + emtricitabine (Emtriva™; FTC); available as Truvada™**

Preferred dosing
- TDF: 300 mg once daily
- FTC: 200 mg once daily
- As Truvada™: one tablet daily

Dosage forms
- TDF: 300 mg tablet
- FTC: see FTC
- Truvada™ (TDF 300 mg plus FTC 200 mg)

Advantages
- FTC: see above
- TDF
  - Convenient dosing (single pill once daily)
  - Resistance profile activity against certain thymidine analogue mutations
  - Well tolerated

Disadvantages
- TDF
  - Same class warnings as NRTIs
  - Drug interactions
  - Increased TDF concentrations among persons taking atazanavir and lopinavir/ritonavir; need to monitor patients for TDF-associated toxicities
  - Preferred dosing of atazanavir if used with TDF: 300 mg + ritonavir 100 mg once daily + TDF 300 mg once daily

ALTERNATE BASIC REGIMENS

- **Lamivudine (Epivir®; 3TC) + stavudine (Zerit®; d4T)**

Preferred dosing
- 3TC: 300 mg once daily or 150 mg twice daily
- d4T: 40 mg twice daily (can use lower doses of 20–30 mg twice daily if toxicity occurs; equally effective but less toxic among HIV-infected patients with peripheral neuropathy); 30 mg twice daily if body weight is <60 kg

Dosage forms
- 3TC: see above
- d4T: 15, 20, 30, and 40 mg tablet

Advantages
- 3TC: see above
- d4T: gastrointestinal (GI) side effects rare

Disadvantages
- Possibility that source-patient virus is resistant to this regimen
- Potential for delayed toxicity (oncogenic/teratogenic) unknown

- **Emtricitabine (Emtriva™; FTC) + stavudine (Zerit®; d4T)**

Preferrred dosing
- FTC: 200 mg daily
- d4T: 40 mg twice daily (can use lower doses of 20–30 mg twice daily if toxicity occurs; equally effective but less toxic among HIV-infected patients who developed peripheral neuropathy); if body weight is <60 kg, 30 mg twice daily

Dosage forms
- FTC: see above
- d4T: see above

Advantages
- 3TC and FTC: see above; d4T's GI side effects rare

Disadvantages
- Potential that source-patient virus is resistant to this regimen
- Unknown potential for delayed toxicity (oncogenic/teratogenic) unknown

- **Lamivudine (Epivir®; 3TC) + didanosine (Videx®; ddI)**

Preferred dosing
- 3TC: 300 mg once daily or 150 mg twice daily
- ddI: Videx® chewable/dispersible buffered tablets can be administered on an empty stomach as either 200 mg twice daily or 400 mg once daily. Patients must take at least two of the appropriate strength tablets at each dose to provide adequate buffering and prevent gastric acid degradation of ddI. Because of the need for adequate buffering, the 200-mg strength tablet should be used only as a component of a once-daily regimen. The dose is either 200 mg twice daily or 400 mg once daily for patients weighing >60 kg and 125 mg twice daily or 250 mg once daily for patients weighing >60 kg.

Dosage forms
- 3TC: 150 or 300 mg tablets
- ddI: 25, 50, 100, 150, or 200 mg buffered white tablets

Advantages
- ddI: once daily dosing option
- 3TC: see above

Disadvantages
- Tolerability: diarrhea more common with buffered preparation than with enteric-coated preparation
- Associated with toxicity: peripheral neuropathy, pancreatitis, and lactic acidosis
- Must be taken on empty stomach except with TDF
- Drug interactions
- 3TC: see above

- **Emtricitabine (Emtriva™; FTC) + didanosine (Videx®; ddI)**

Preferred dosing
- FTC: 200 mg once daily
- ddI: see above

Dosage forms
- ddI: see above
- FTC: see above

Advantages
- ddI: see above
- FTC: see above

Disadvantages
- Tolerability: diarrhea more common with buffered than with enteric-coated preparation
- Associated with toxicity: peripheral neuropathy, pancreatitis, and lactic acidosis
- Must be taken on empty stomach except with TDF
- Drug interactions
- FTC: see above

PREFERRED EXPANDED REGIMEN

Basic regimen plus:

- **Lopinavir/ritonavir (Kaletra®; LPV/RTV)**

Preferred dosing
- LPV/RTV: 400/100 mg = 3 capsules twice daily with food

Dosage form
- LPV/RTV: 133/33 mg capsules

Advantages
- Potent HIV protease inhibitor
- Generally well-tolerated

Disadvantages
- Potential for serious or life-threatening drug interactions (see Table 4)
- Might accelerate clearance of certain drugs, including oral contraceptives (requiring alternative or additional contraceptive measures for women taking these drugs)
- Can cause severe hyperlipidemia, especially hypertriglyceridemia
- GI (e.g., diarrhea) events common

ALTERNATE EXPANDED REGIMENS

Basic regimen plus one of the following:

- **Atazanavir (Reyataz®; ATV) ± ritonavir (Norvir®; RTV)**

Preferred dosing
- ATV: 400 mg once daily, unless used in combination with TDF, in which case ATV should be boosted with RTV, preferred dosing of ATV 300 mg + RTV: 100 mg once daily

Dosage forms
- — ATV: 100, 150, and 200 mg capsules
- — RTV: 100 mg capsule

Advantages
- — Potent HIV protease inhibitor
- — Convenient dosing – once daily
- — Generally well tolerated

Disadvantages
- — Hyperbilirubinemia and jaundice common
- — Potential for serious or life-threatening drug interactions (see Table 4)
- — Avoid coadministration with proton pump inhibitors
- — Separate antacids and buffered medications by 2 hours and H2-receptor antagonists by 12 hours to avoid decreasing ATV levels
- — Caution should be used with ATV and products known to induce PR prolongation (e.g., diltiazem)

- **Fosamprenavir (Lexiva®; FOSAPV) ± ritonavir (Norvir®; RTV)**

Preferred dosing
- — FOSAPV: 1400 mg twice daily (without RTV)
- — FOSAPV: 1400 mg once daily + RTV 200 mg once daily
- — FOSAPV: 700 mg twice daily + RTV 100 mg twice daily

Dosage form
- — FOSAPV: 700 mg tablets
- — RTV: 100 mg capsule

Advantages
- — Once daily dosing when given with ritonavir

Disadvantages
- — Tolerability: GI side effects common
- — Multiple drug interactions. Oral contraceptives decrease fosamprenavir concentrations
- — Incidence of rash in healthy volunteers, especially when used with low doses of ritonavir. Differentiating between early drug-associated rash and acute seroconversion can be difficult and cause extraordinary concern for the exposed person

- **Indinavir (Crixivan®; IDV) ± ritonavir (Norvir®; RTV)**

Preferred dosing
- — IDV 800 mg + RTV 100 mg twice daily without regard to food

Alternative dosing
- — IDV: 800 mg every 8 hours, on an empty stomach

Dosage forms
- — IDV: 200 mg, 333, and 400 mg capsule
- — RTV: 100 mg capsule

Advantages
- — Potent HIV inhibitor

Disadvantages
- — Potential for serious or life-threatening drug interactions (see Table 4)
- — Serious toxicity (e.g., nephrolithiasis) possible; consumption of 8 glasses of fluid/day required
- — Hyperbilirubinemia common; must avoid this drug during late pregnancy
- — Requires acid for absorption and cannot be taken simultaneously with ddI, chewable/dispersible buffered tablet formulation (doses must be separated by ≥1 hour)

- **Saquinavir (Invirase®; SQV) + ritonavir (Norvir®; RTV)**

Preferred dosing
- — SQV: 1,000 mg (given as Invirase) + RTV 100 mg, twice daily
- — SQV : five capsules twice daily + RTV: one capsule twice daily

Dosage forms
- — SQV (Invirase): 200 mg capsule
- — RTV: 100 mg capsule

Advantages
- — Generally well-tolerated, although GI events common

Disadvantages
- — Potential for serious or life-threatening drug interactions (see Table 4)
- — Substantial pill burden

- **Nelfinavir (Viracept®; NFV)**

Preferred dosing
- — NFV: 1,250 mg (2 x 625 mg or 5 x 250 mg tablets), twice daily with a meal

Dosage forms
- — NFV: 250 or 625 mg tablet

Advantages
- — Generally well-tolerated

Disadvantages
- — Diarrhea or other GI events common
- — Potential for serious and/or life-threatening drug interactions (see Table 4)

- **Efavirenz (Sustiva®; EFV)**

Preferred dosing
- — EFV: 600 mg daily, at bedtime

Dosage forms
- — EFV: 50, 100, 200 capsules
- — EFV: 600 mg tablet

Advantages
- — Does not require phosphorylation before activation and might be active earlier than other antiretroviral agents (a theoretic advantage of no demonstrated clinical benefit)
- — Once daily dosing

Disadvantages
- — Drug associated with rash (early onset) that can be severe and might rarely progress to Stevens-Johnson syndrome
- — Differentiating between early drug-associated rash and acute seroconversion can be difficult and cause extraordinary concern for the exposed person
- — Central nervous system side effects (e.g., dizziness, somnolence, insomnia, or abnormal dreaming) common; severe psychiatric symptoms possible (dosing before bedtime might minimize these side effects)
- — Teratogen; should not be used during pregnancy
- — Potential for serious or life-threatening drug interactions (see Table 5)

ANTIRETROVIRAL AGENTS GENERALLY NOT RECOMMENDED FOR USE AS PEP

- **Nevirapine (Viramune®; NVP)**

Disadvantages
- — Associated with severe hepatotoxicity (including at least one case of liver failure requiring liver transplantation in an exposed person taking PEP)
- — Associated with rash (early onset) that can be severe and progress to Stevens-Johnson syndrome
- — Differentiating between early drug-associated rash and acute seroconversion can be difficult and cause extraordinary concern for the exposed person
- — Drug interactions: can lower effectiveness of certain antiretroviral agents and other commonly used medicines

- **Delavirdine (Rescriptor®; DLV)**

Disadvantages
- — Drug associated with rash (early onset) that can be severe and progress to Stevens-Johnson syndrome
- — Multiple drug interactions

- **Abacavir (Ziagen®; ABC)**

Disadvantages
- — Severe hypersensitivity reactions can occur, usually within the first 6 weeks
- — Differentiating between early drug-associated rash/hypersensitivity and acute seroconversion can be difficult

- **Zalcitabine (Hivid®; ddC)**

Disadvantages
- — Three times a day dosing
- — Tolerability
- — Weakest antiretroviral agent

ANTIRETROVIRAL AGENT FOR USE AS PEP ONLY WITH EXPERT CONSULTATION

- **Enfuvirtide (Fuzeon™; T20)**

Preferred dosing
- — T20: 90 mg (1 ml) twice daily by subcutaneous injection

Dosage forms
- — T20: Single-dose vial, reconstituted to 90 mg/ml

Advantages
- — New class
- — Unique viral target; to block cell entry
- — Prevalence of resistance low

Disadvantages
- — Twice-daily injection
- — Safety profile: local injection site reactions
- — Never studied among antiretroviral-naïve or HIV-negative patients
- — False-positive EIA HIV antibody tests might result from formation of anti-T20 antibodies that cross-react with anti-gp41 antibodies

PHS Working Group on Occupational Postexposure Prophylaxis: Adelisa L Panlilio, Denise M. Cardo, Division of Healthcare Quality Promotion, National Center for Infectious Diseases, CDC; Lisa A. Grohskopf; Walid Heneine, Division of HIV/AIDS Prevention, National Center for HIV, STD, and TB Prevention, CDC; Clara Sue Ross, Ahmed Gomaa; Division of Surveillance and Hazard Evaluations, and Field Studies, National Institute for Occupational Safety and Health, CDC; Kimberly A. Struble, Center for Drug Evaluation and Research, FDA; Abe Macher, HIV/AIDS Bureau, HRSA; David K Henderson, Clinical Center, National Institutes of Health.

Recommendations and Reports | September 30, 2005 / Vol. 54 / No. RR-9

Continuing Education Activity Sponsored by CDC

Updated U.S. Public Health Service Guidelines for the Management of Occupational Exposures to HIV and Recommendations for Postexposure Prophylaxis

EXPIRATION — September 30, 2007

You must complete and return the response form electronically or by mail by **September 30, 2007**, to receive continuing education credit. If you answer all of the questions, you will receive an award letter for 1.5 hours Continuing Medical Education (CME) credit; 0.15 Continuing Education Units (CEUs); or 1.9 contact hours Continuing Nursing Education (CNE) credit. If you return the form electronically, you will receive educational credit immediately. If you mail the form, you will receive educational credit in approximately 30 days. No fees are charged for participating in this continuing education activity.

INSTRUCTIONS

By Internet

1. Read this *MMWR* (Vol. 54, RR-9), which contains the correct answers to the questions beginning on the next page.
2. Go to the *MMWR* Continuing Education Internet site at http://www.cdc.gov/mmwr/cme/conted.html.
3. Select which exam you want to take and select whether you want to register for CME, CEU, or CNE credit.
4. Fill out and submit the registration form.
5. Select exam questions. To receive continuing education credit, you must answer all of the questions. Questions with more than one correct answer will instruct you to "Indicate all that apply."
6. Submit your answers no later than **September 30, 2007**
7. Immediately print your Certificate of Completion for your records.

By Mail or Fax

1. Read this *MMWR* (Vol. 54, RR-9), which contains the correct answers to the questions beginning on the next page.
2. Complete all registration information on the response form, including your name, mailing address, phone number, and e-mail address, if available.
3. Indicate whether you are registering for CME, CEU, or CNE credit.
4. Select your answers to the questions, and mark the corresponding letters on the response form. To receive continuing education credit, you must answer all of the questions. Questions with more than one correct answer will instruct you to "Indicate all that apply."
5. Sign and date the response form or a photocopy of the form and send no later than **September 30, 2007**, to
   Fax: 770-488-8555 Mail: MMWR CE Credit
   Division of Scientific Communications
   Coordinating Center for Health Information and Service, MS K-95
   Centers for Disease Control and Prevention
   1600 Clifton Rd, N.E.
   Atlanta, GA 30333
6. Your Certificate of Completion will be mailed to you within 30 days.

ACCREDITATION

Continuing Medical Education (CME). CDC is accredited by the Accreditation Council for Continuing Medical Education (ACCME) to provide continuing medical education for physicians. CDC designates this educational activity for a maximum of 1.5 hours in category 1 credit toward the AMA Physician's Recognition Award. Each physician should claim only those hours of credit that he/she actually spent in the educational activity.

Continuing Education Unit (CEU). CDC has been approved as an authorized provider of continuing education and training programs by the International Association for Continuing Education and Training and awards 0.15 Continuing Education Units (CEUs).

Continuing Nursing Education (CNE). This activity for 1.9 contact hours is provided by CDC, which is accredited as a provider of continuing education in nursing by the American Nurses Credentialing Center's Commission on Accreditation.

DEPARTMENT OF HEALTH AND HUMAN SERVICES
CENTERS FOR DISEASE CONTROL AND PREVENTION

Goal and Objectives

This report provides recommendations regarding clinical practice for managing occupational exposures to HIV in health-care settings, including appropriate use of HIV postexposure prophylaxis (PEP). The goal of this report is to provide recommendations for guiding clinical practice in managing PEP for health-care personnel (HCP) with occupational exposure to HIV. Upon completion of this educational activity, the reader should be able to a) describe occupational exposures for which exposure management is appropriate; b) describe the appropriate selection of HIV PEP; c) describe the appropriate use of HIV PEP; d) describe the follow-up evaluation of exposed HCP; e) describe the follow-up counseling of exposed HCP; and f) list situations for which expert consultation in the management of occupational exposures is recommended.

To receive continuing education credit, please answer all of the following questions.

1. Contact with which body fluid(s) poses a risk for HIV transmission in health-care settings? (*Indicate all that apply.*)

A. Blood.
B. Urine.
C. Sweat.
D. Amniotic fluid.
E. A and D.
F. B and C.

2. What is the recommended duration of HIV PEP for occupational exposures to HIV? (*Choose the one correct answer.*)

A. 7 days.
B. 14 days.
C. 21 days.
D. 28 days.
E. 2 months.

3. What is the recommended time to initiation of HIV PEP after exposure when PEP is indicated? (*Choose the one correct answer.*)

A. 2 days.
B. 24–48 hours.
C. As soon as possible (preferably within hours).

4. Follow-up after occupational exposures to HIV should include which of the following? (*Choose the one correct answer.*)

A. Serologic follow-up for HIV infection.
B. Monitoring for adverse effects of HIV postexposure prophylaxis if taken.
C. Monitoring for acute seroconversion illness.
D. Counseling on adherence with HIV PEP and the emotional stress of dealing with exposures.
E. All of the above.

5. The potential for interactions with other medications is greatest for which of the antiretroviral drug classes recommended for HIV postexposure prophylaxis? (*Choose the one correct answer.*)

A. Reverse transcriptase inhibitors (nucleoside analogues).
B. Nonnucleoside reverse transcriptase inhibitors.
C. Protease inhibitors.
D. A and B.
E. B and C.
F. A and C.

6. Which antiretrovirals are not currently recommended for use by pregnant HCP? (*Indicate all that apply.*)

A. Efavirenz.
B. Zidovudine.
C. Nelfinavir.
D. Tenofovir.

7. Resistance testing of the source-patient after an exposure should always be performed to help in selection of HIV postexposure prophylaxis regimens.

A. True.
B. False.

8. Adverse effects of antiretroviral HIV postexposure prophylaxis are uncommonly reported by HCP.

A. True.
B. False.

9. Which types of exposure pose a risk for HIV transmission in health-care settings? (*Indicate all that apply.*)

A. Intact skin exposure to blood.
B. Mucous membrane splash of urine.
C. Needlestick injury after phlebotomy.
D. Splash of blood on abraded skin.
E. C and D.
F. A and B.

10. A 12-month serologic follow-up after an occupational exposure to HIV is recommended in which situation(s)? (*Indicate all that apply.*)

A. Any percutaneous exposure to an HIV-infected source.
B. If the exposed worker takes HIV postexposure prophylaxis.
C. If the exposure source is coinfected with HIV and HCV and becomes HCV-infected.
D. None of the above.

11. Which best describes your professional activities:

A. Physician.
B. Nurse.
C. Health educator.
D. Office staff.
E. Other.

12. I plan to use these recommendations as the basis for …(*Indicate all that apply.*)

A. health education materials.
B. insurance reimbursement policies.
C. local practice guidelines.
D. public policy.
E. other.

13. Overall, the length of the journal article was…

A. much too long.
B. a little too long.
C. just right.
D. a little too short.
E. much too short.

14. After reading this report, I am confident I can describe occupational exposures for which exposure management is appropriate.

A. Strongly agree.
B. Agree.
C. Undecided.
D. Disagree.
E. Strongly disagree.

15. After reading this report, I am confident I can describe the appropriate selection of HIV PEP.

A. Strongly agree.
B. Agree.
C. Undecided.
D. Disagree.
E. Strongly disagree.

16. After reading this report, I am confident I can describe the appropriate use of HIV PEP.

A. Strongly agree.
B. Agree.
C. Undecided.
D. Disagree.
E. Strongly disagree.

17. After reading this report, I am confident I can describe the follow-up evaluation of exposed HCP.

A. Strongly agree.
B. Agree.
C. Undecided.
D. Disagree.
E. Strongly disagree.

18. After reading this report, I am confident I can describe the follow-up counseling of exposed HCP.

A. Strongly agree.
B. Agree.
C. Undecided.
D. Disagree.
E. Strongly disagree.

19. After reading this report, I am confident I can list situations for which expert consultation in the management of occupational exposures is recommended.

A. Strongly agree.
B. Agree.
C. Undecided.
D. Disagree.
E. Strongly disagree.

20. The learning outcomes (objectives) were relevant to the goal of this report.

A. Strongly agree.
B. Agree.
C. Undecided.
D. Disagree.
E. Strongly disagree.

21. The instructional strategies used in this report (text, tables, boxes, and appendix) helped me learn the material.

A. Strongly agree.
B. Agree.
C. Undecided.
D. Disagree.
E. Strongly disagree.

22. The content was appropriate given the stated objectives of the report.

A. Strongly agree.
B. Agree.
C. Undecided.
D. Disagree.
E. Strongly disagree.

***MMWR* Response Form for Continuing Education Credit**
September 30, 2005/Vol. 54/No. RR-9

Updated U.S. Public Health Service Guidelines for the Management of Occupational Exposures to HIV and Recommendations for Postexposure Prophylaxis

To receive continuing education credit, you must
1. provide your contact information (**please print or type**);
2. indicate your choice of CME, CME for nonphysicians, CEU, or CNE credit;
3. answer all of the test questions;
4. sign and date this form or a photocopy;
5. submit your answer form by September 30, 2007.

Failure to complete these items can result in a delay or rejection of your application for continuing education credit.

Incorporating HIV Prevention into the Medical Care of Persons Living with HIV

Recommendations of CDC, the Health Resources and Services Administration, the National Institutes of Health, and the HIV Medicine Association of the Infectious Diseases Society of America

Summary

Reducing transmission of human immunodeficiency virus (HIV) in the United States requires new strategies, including emphasis on prevention of transmission by HIV-infected persons. Through ongoing attention to prevention, risky sexual and needle-sharing behaviors among persons with HIV infection can be reduced and transmission of HIV infection prevented. Medical care providers can substantially affect HIV transmission by screening their HIV-infected patients for risk behaviors; communicating prevention messages; discussing sexual and drug-use behavior; positively reinforcing changes to safer behavior; referring patients for services such as substance abuse treatment; facilitating partner notification, counseling, and testing; and identifying and treating other sexually transmitted diseases (STDs).

To help incorporate HIV prevention into the medical care of HIV-infected persons, CDC, the Health Resources and Services Administration, the National Institutes of Health, and the HIV Medicine Association of the Infectious Diseases Society of America developed these recommendations. The recommendations are general and apply to incorporating HIV prevention into the medical care of all HIV-infected adolescents and adults, regardless of age, sex, or race/ethnicity. They are intended for all persons who provide medical care to HIV-infected persons (e.g., physicians, nurse practitioners, nurses, physician assistants); they might also be useful to those who deliver prevention messages (e.g., case managers, social workers, health educators).

The recommendations were developed by using an evidence-based approach. For each recommendation, the strength of the recommendation, the quality of available evidence supporting the recommendation, and the outcome for which the recommendation is rated are provided. The recommendations are categorized into three major components: screening for HIV transmission risk behaviors and STDs, providing brief behavioral risk-reduction interventions in the office setting and referring selected patients for additional prevention interventions and other related services, and facilitating notification and counseling of sex and needle-sharing partners of infected persons.

Introduction

Despite substantial advances in the treatment of human immunodeficiency virus (HIV) infection, the estimated number of annual new HIV infections in the United States has remained at 40,000 for over 10 years (*1*). HIV prevention in this country has largely focused on persons who are not HIV infected, to help them avoid becoming infected. However, further reduction of HIV transmission will require new strategies, including increased emphasis on preventing transmission by HIV-infected persons (*2,3*). HIV-infected persons who are aware of their HIV infection tend to reduce behaviors that might transmit HIV to others (*4–7*). Nonetheless, recent reports suggest that such behavioral changes often are not maintained and that a substantial number of HIV-infected persons continue to engage in behaviors that place others at risk for HIV infection (*8–13*).

Reversion to risky sexual behavior might be as important in HIV transmission as failure to adopt safer sexual behavior immediately after receiving a diagnosis of HIV (*14*). Unprotected anal sex appears to be occurring more frequently in some urban centers, particularly among young men who have sex with men (MSM) (*15*). Bacterial and viral sexually transmitted diseases (STDs) in HIV-infected men and women receiving outpatient care have been increasingly noted (*16,17*), indicating ongoing risky behaviors and opportunities for HIV

The material in this report originated in the National Center for HIV, STD and TB Prevention, Harold W. Jaffe, M.D., Director; Division of HIV/AIDS Prevention — Surveillance and Epidemiology, Robert S. Janssen, Director; Division of HIV/AIDS Prevention — Intervention, Research, and Support, Robert S. Janssen, M.D., Acting Director.

transmission. Further, despite declining syphilis prevalence in the general U.S. population, sustained outbreaks of syphilis among MSM, many of whom are HIV infected, continue to occur in some areas; rates of gonorrhea and chlamydial infection have also risen for this population (*18–21*). Rising STD rates among MSM indicate increased potential for HIV transmission, both because these rates suggest ongoing risky behavior and because STDs have a synergistic effect on HIV infectivity and susceptibility (*22*). Studies suggest that optimism about the effectiveness of highly active antiretroviral therapy (HAART) for HIV may be contributing to relaxed attitudes toward safer sex practices and increased sexual risk-taking by some HIV-infected persons (*12,23–27*).

Injection drug use also continues to play a key role in the HIV epidemic; at least 28% of AIDS cases among adults and adolescents with known HIV risk category reported to CDC in 2000 were associated with injection drug use (*28*). In some large drug-using communities, HIV seroincidence and seroprevalence among injection drug users (IDUs) have declined in recent years (*29,30*). This decline has been attributed to several factors, including increased use of sterile injection equipment, declines in needle-sharing, shifts from injection to noninjection methods of using drugs, and cessation of drug use (*31–33*). However, injection-drug use among young adult heroin users has increased substantially in some areas (*34,35*), a reminder that, as with sexual behaviors, changes to less risky behaviors may be difficult to sustain.

Clinicians providing medical care to HIV-infected persons can play a key role in helping their patients reduce risk behaviors and maintain safer practices and can do so with a feasible level of effort, even in constrained practice settings. Clinicians can greatly affect patients' risks for transmission of HIV to others by performing a brief screening for HIV transmission risk behaviors; communicating prevention messages; discussing sexual and drug-use behavior; positively reinforcing changes to safer behavior; referring patients for such services as substance abuse treatment; facilitating partner notification, counseling, and testing; and identifying and treating other STDs (*36,37*). These measures may also decrease patients' risks of acquiring other STDs and bloodborne infections (e.g., viral hepatitis). Managed care plans can play an important role in HIV prevention by incorporating these recommendations into their practice guidelines, educating their providers and enrollees, and providing condoms and educational materials. In the context of care, prevention services might be delivered in clinic or office environments or through referral to community-based programs. Some clinicians have expressed concern that reimbursement is often not provided for prevention services and note that improving reimbursement for such services might enhance the adoption and implementation of these guidelines.

This report provides general recommendations for incorporating HIV prevention into the medical care of all HIV-infected adolescents and adults, regardless of age, sex, or race/ethnicity. The recommendations are intended for all persons who provide medical care to HIV-infected persons (e.g., physicians, nurse practitioners, nurses, physician assistants). They may also be useful to those who deliver prevention messages (e.g., case managers, social workers, health educators). Special considerations may be needed for some subgroups (e.g., adolescents, for whom laws and regulations might exist governing providing of services to minors, the need to obtain parental consent, or duty to inform). However, it is beyond the scope of this report to address special considerations of subgroups. Furthermore, the recommendations focus on sexual and drug-injection behaviors, since these behaviors are responsible for nearly all HIV transmission in the United States. Separate guidelines have been published for preventing perinatal transmission (*38–40*).

These recommendations were developed by using an evidence-based approach (Table 1). The strength of each recommendation is indicated on a scale of A (strongest recommendation for) to E (recommendation against); the quality of available evidence supporting the recommendation is indicated on a scale of I (strongest evidence for) to III (weakest evidence for), and the outcome for which the recommendation is rated is provided. The recommendations are categorized into three

TABLE 1. Rating systems for strength of recommendations and quality of evidence supporting the recommendations

Rating	Strength of the Recommendation
A	**Should always be offered.** Both strong evidence for efficacy and substantial benefit support recommendation for use.
B	**Should generally be offered.** Moderate evidence for efficacy — or strong evidence for efficacy but only limited benefit — supports recommendation for use.
C	**Optional.** Evidence for efficacy is insufficient to support a recommendation for use.
D	**Should generally not be offered.** Moderate evidence for lack of efficacy or for adverse outcome supports a recommendation against use.
E	**Should never be offered.** Good evidence for lack of efficacy or for adverse outcome supports a recommendation against use.
	Quality of Evidence Supporting the Recommendation
I	Evidence from at least one properly randomized, controlled trial.
II	Evidence from at least one well-designed clinical trial without randomization, from cohort or case-controlled analytic studies (preferably from more than one center), or from multiple time-series studies. Or dramatic results from uncontrolled experiments.
III	Evidence from opinions of respected authorities based on clinical experience, descriptive studies, or reports of expert committees.

major components: 1) screening for HIV transmission risk behaviors and STDs, 2) providing brief behavioral risk-reduction interventions in the office setting and referring selected patients for additional prevention interventions and other related services, and 3) facilitating notification and counseling of sex and needle-sharing partners of infected persons.

This report was developed by CDC, the Health Resources and Services Administration (HRSA), the National Institutes of Health (NIH), and the HIV Medicine Association (HIVMA) of the Infectious Diseases Society of America (IDSA). The recommendations will evolve as results from ongoing behavioral intervention trials become available.

Risk Screening

Risk screening is a brief assessment of behavioral and clinical factors associated with transmission of HIV and other STDs (Table 2). Risk screening can be used to identify patients who should receive more in-depth risk assessment and HIV risk-reduction counseling, other risk-reduction interventions, or referral for other services (e.g., substance abuse treatment). Risk screening identifies patients at greatest risk for transmitting HIV so that prevention and referral recommendations can be focused on these patients. Screening methods include probing for behaviors associated with transmission of HIV and other STDs, eliciting patient reports of symptoms of other STDs, and laboratory testing for other STDs. Although each of these methods has limitations, a combination of methods should increase the sensitivity and effectiveness of screening. In conducting risk screening, clinicians should recognize that risk is not static. Patients' lives and circumstances change, and a patient's risk of transmitting HIV may change from one medical encounter to another. Also, clinicians should recognize that working with adolescents may require special approaches and should be aware of and adhere to all laws and regulations related to providing services to minors.

Screening for Behavioral Risk Factors

Clinicians frequently believe that patients are uncomfortable disclosing personal risks and hesitant to respond to questions about sensitive issues, such as sexual behaviors and illicit drug use. However, available evidence suggests that patients, when asked, will often disclose their risks (*41,42*) and that some patients have reported greater confidence in their clinician's ability to provide high-quality care if asked about sexual and STD history during the initial visits (*43*).

Screening for behavioral risk factors can be done with brief self-administered written questionnaires; computer-, audio-, and video-assisted questionnaires; structured face-to-face

TABLE 2. Recommendations for screening of human immunodeficiency virus (HIV)-infected persons for HIV transmission risk

Recommendation	Rating
HIV-infected patients should be screened for behaviors associated with HIV transmission by using a straightforward, nonjudgmental approach. This should be done at the initial visit and subsequent routine visits or periodically, as the clinician feels necessary, but at a minimum of yearly. Any indication of risky behavior should prompt a more thorough assessment of HIV transmission risks.	A-II (for identifying transmission risk)
At the initial and each subsequent routine visit, HIV-infected patients should be questioned about symptoms of STDs (e.g., urethral or vaginal discharge; dysuria; intermenstrual bleeding; genital or anal ulcers; anal pruritus, burning, or discharge; and, for women, lower abdominal pain with or without fever). Regardless of reported sexual behavior or other epidemiologic risk information, the presence of such signs or symptoms should always prompt diagnostic testing and, when appropriate, treatment.	A-I (for identifying and treating STDs)
At the initial visit • All HIV-infected women and men should be screened for laboratory evidence of syphilis. Women should also be screened for trichomoniasis. Sexually active women aged ≤25 years and other women at increased risk, even if asymptomatic, should be screened for cervical chlamydial infection.	A-II (for identifying STDs)
• Consideration should be given to screening all HIV-infected men and women for gonorrhea and chlamydial infections. However, because of the cost of screening and the variability of prevalence of these infections, decisions about routine screening for these infections should be based on epidemiologic factors (including prevalence of infection in the community or the population being served), availability of tests, and cost. (Some HIV specialists also recommend type-specific serologic testing for herpes simplex virus type 2 for both men and women.).	B-II (for identifying STDs)
Screening for STDs should be repeated periodically (i.e., at least annually) if the patient is sexually active or if earlier screening revealed STDs. Screening should be done more frequently (e.g., at 3–6-month intervals) for asymptomatic persons at higher risk (see Box 2).	B-III (for identifying STDs)
At the initial and each subsequent routine visit, HIV-infected women of childbearing age should be questioned to identify possible current pregnancy, interest in future pregnancy, or sexual activity without reliable contraception. They should be referred for appropriate counseling, reproductive health care, or prenatal care, as indicated. Women should be asked whether they suspect pregnancy or have missed their menses and, if so, should be tested for pregnancy.	A-I (for preventing perinatal HIV transmission)

interviews; and personalized discussions (*41,44–53*). Screening questions can be either open-ended or closed (directed) (Box 1). Use of open-ended questions avoids simple "yes" or "no" responses and encourages patients to discuss personal risks and the circumstances in which risks occur (*15,44,54*). Open-ended questions also help the clinician gather enough detail to understand potential transmission risks and make more meaningful recommendations. However, although well received by patients, the open-ended approach may initially be difficult for clinicians schooled in directed questioning, who tend to prefer directed screening questions. Directed questions are probably useful for identifying patients with problems that should be more thoroughly discussed. Among directed approaches, technical tools like computer-, audio-, and video-assisted interviews have been found to elicit more self-reported risk behaviors than did interviewer-administered questionnaires, particularly among younger patients (*41,51–53,55*). Studies suggest that clinicians who receive some training, particularly that including role-play and feedback concerning clinical performance, are more likely to perform effective risk screening (*46–49*).

Sex-related behaviors important to address in risk screening include whether the patient has been engaging in sex; number and sex of partners; partners' HIV serostatus (infected, not infected, or unknown); types of sexual activity (oral, vaginal, or anal sex) and whether condoms are used; and barriers to abstinence or correct condom use (e.g., difficulty talking with partners about or disclosing HIV serostatus, alcohol and other drug use before or during sex). Also, because the risk for perinatal HIV transmission is high without appropriate intervention, clinicians are advised to assess whether women of childbearing age might be pregnant, are interested in becoming pregnant, or are not specifically considering pregnancy but are sexually active and not using reliable contraception (*39,56,57*). Women who are unable to become pregnant because of elective sterilization, hysterectomy, salpingo-oophorectomy, or other medical reasons might be less likely to use condoms because of a lack of concern for contraception; these women should be counseled regarding the need for use of condoms to prevent transmission of HIV. Patients who wish to conceive and whose partner is not infected also might engage in risky behavior. Patients interested in pregnancy, for themselves or their partner, should be referred to a reproductive health specialist (*58*).

Injection-drug–related behaviors important to address in screening include whether the patient has been injecting illicit drugs; whether the patient has been sharing needles and syringes or other injection equipment; how many partners the patient has shared needles with; whether needle-sharing partners are known to be HIV infected, not infected, or of

BOX 1. Examples of screening strategies to elicit patient-reported risk for human immunodeficiency virus (HIV) transmission*

Open-ended question by clinician, similar to one of the following:

- "What are you doing now that you think may be a risk for transmitting HIV to a partner?"
- "Tell me about the people you've had sex with recently."
- "Tell me about your sex life."

Screening questions (checklist) for use with a self-administered questionnaire; computer-, audio-, or video-assisted questionnaire; or a face-to-face interview: †§

"Since your last checkup here," or, if first visit, "Since you found out you were infected with HIV,":

- "Have you been sexually active; that is, have you had vaginal, anal, or oral sex with a partner?"

If yes

— "Have you had vaginal or anal intercourse without a condom with anyone?"

If yes

— "Were any of these people HIV-negative, or are you unsure about their HIV status?"

— "Have you had oral sex with someone?"

If yes

— (For a male patient) "Did you ejaculate into your partner's mouth?"

- "Have you had a genital sore or discharge, discomfort when you urinate, or anal burning or itching?"
- "Have you been diagnosed or treated for a sexually transmitted disease (STD), or do you know if any of your sex partners have been diagnosed or treated for an STD?"
- "Have you shared drug-injection equipment (needles, syringes, cotton, cooker, water) with others?"

If yes

— "Were any of these people HIV negative, or are you unsure about their HIV status?"

* Source: Adapted from CDC. Revised guidelines for HIV counseling, testing, and referral. MMWR 2001;50(No. RR-19).

† This checklist can be administered by the patient or clinician and should take approximately 4 minutes.

§ A positive response to any of the screening questions should cue the clinician to have a more in-depth discussion to ensure that specific risks are clearly understood.

unknown HIV serostatus; whether the patient has been using new or sterilized needles and syringes; and what barriers exist to ceasing illicit drug use or, failing that, to adopting safer injection practices (e.g., lack of access to sterile needles and syringes).

Approaches to Screening for Behavioral Risk Factors

The most effective manner for screening for behavioral risk factors is not well defined; however, simple approaches are more acceptable to both patients and health-care providers (*53*). Screening tools should be designed to be as sensitive as possible for identifying behavioral risks; a more detailed, personalized assessment can then be used to improve specificity and provide additional detail. The sensitivity of screening instruments depends on obtaining accurate information. However, accuracy of information can be influenced by a variety of factors: recall, misunderstanding about risk, legal concerns, concern about confidentiality of the information and how the information will be used, concern that answers may affect ability to receive services, concern that answers may affect social desirability (i.e., the tendency to provide responses that will avoid criticism), and the desire for social approval (the tendency to seek praise) (*45,55*). Interviewer factors also influence the accuracy of information. Surveys indicate that patients are more likely to discuss risk behaviors if they perceive their clinicians are comfortable talking about stigmatized topics such as sex and drug use (*46–49*) and are nonjudgmental, empathetic, knowledgeable, and comfortable counseling patients about sexual risk factors (*41,46–50*). These factors need to be considered when interpreting responses to screening questions. To the extent possible, screening and interventions should be individualized to meet patient needs. Examples of two screening approaches are provided (Box 1).

Incorporating Screening for Behavioral Risk Factors into the Office Visit

Before the patient is seen by the clinician, screening for behavioral risks can be done with a self-administered questionnaire; a computer-, audio-, or video-assisted questionnaire; or a brief interview with ancillary staff; the clinician can then review the results on the patient's medical record. Alternatively, behavioral risk screening can be done during the medical encounter (e.g., as part of the history); either open-ended questions or a checklist approach with in-depth discussion about positive responses can be used (Box 1). Because, given patients' immediate health needs, it can be difficult in the clinical care setting to remember less urgent matters such as risk screening and harm reduction, provider reminder systems (e.g., computerized reminders) have been used by health-care systems to help ensure that recommended procedures are done regularly. Multicomponent health-care system interventions that include a provider reminder system and a provider education program are effective in increasing delivery of certain prevention services (*59*). Risk screening might be more likely to occur in managed care settings if the managed care organization specifically calls for it (*60*).

Screening for Clinical Risk Factors

Screening for STDs

Recommendations for preventive measures, including medical screening and vaccinations, that should be included in the care of HIV-infected persons (*16,21,39,44,54,61–69*) have been published previously. This report is not intended to duplicate existing recommendations; it addresses screening specifically to identify clinical factors associated with increased risk for transmission of HIV from infected to noninfected persons. In this context, STDs are the primary infections of concern for three reasons. First, the presence of STDs often suggests recent or ongoing sexual behaviors that may result in HIV transmission. Second, many STDs enhance the risk for HIV transmission or acquisition (*22,70–73*). Early detection and treatment of bacterial STDs might reduce the risk for HIV transmission. Third, identification and treatment of STDs can reduce the potential for spread of these infections among high-risk groups (i.e., sex or drug-using networks).

Screening and diagnostic testing serve distinctly different purposes. By definition, screening means testing on the basis of risk estimation, regardless of clinical indications for testing, and is a cornerstone of identifying persons at risk for transmitting HIV to others. Clinicians should routinely ask about STD symptoms, including urethral or vaginal discharge; dysuria; intermenstrual bleeding; genital or anal ulcers or other lesions; anal pain, pruritus, burning, discharge, or bleeding; and, for women, lower abdominal pain with or without fever. Regardless of reported sexual behavior or other epidemiologic risk information, the presence of such symptoms should always prompt diagnostic testing and, when appropriate, treatment. However, clinical symptoms are not sensitive for identifying many infections because most STDs are asymptomatic (*74–81*); therefore, laboratory screening of HIV-infected persons is an essential tool for identifying persons at risk for transmitting HIV and other STDs.

Laboratory Testing for STDs

Identification of syphilis requires direct bacteriologic (i.e., dark-field microscopy) or serologic testing. However, noninvasive, urine-based nucleic acid amplification tests

(NAATs) have greatly simplified testing for *Neisseria gonorrhoeae* and *Chlamydia trachomatis*. Although they are more costly than other screening tests, their ease of use and sensitivity—similar to the sensitivity of culture for detection of *N. gonorrhoeae* and substantially higher than the sensitivity of all other tests for *C. trachomatis* (including culture)—for detecting genital infection are great advantages. Detection of rectal or pharyngeal gonorrhea still requires culture. Pharyngeal infection with *C. trachomatis* is uncommon, and routine screening for it is not recommended (*63,82*). NAATs have not been approved for use with specimens collected from sites other than the urethra, cervix, or urine. Recommended screening strategies and diagnostic tests for detecting asymptomatic STDs are described (Box 2, Table3).

Local and state health departments have reporting requirements, which vary among states, for HIV and other STDs. Clinicians need to be aware of and comply with requirements for the areas in which they practice; information on reporting requirements can be obtained from health departments.

Screening for Pregnancy

Women of childbearing age should be questioned during routine visits about the possibility of pregnancy. Women who state that they suspect pregnancy or have missed their menses

BOX 2. Examples of laboratory screening strategies to detect asymptomatic sexually transmitted diseases*

First Visit

For all patients

- Test for syphilis: nontreponemal serologic test (e.g., rapid plasma reagin [RPR] or Venereal Disease Research Laboratory [VDRL] test).
- Consider testing for urogenital gonorrhea: urethral (men) or cervical (women) specimen for culture, or urethral/cervical specimen or first-catch urine† (men and women) nucleic acid amplification test (NAAT) for *Neisseria gonorrhoeae.*§
- Consider testing for urogenital chlamydial infection: urethral (men) or cervical (women) specimen or first-catch urine† (men and women) specimen for NAAT for *Chlamydia trachomatis.*§

For women

- Test for trichomoniasis: wet mount examination or culture of vaginal secretions for *Trichomonas vaginalis.*
- Test for urogenital chlamydia: cervical specimen for NAAT for *C. trachomatis*§ for all sexually active women aged ≤25 years and other women at increased risk, even if asymptomatic.

For patients reporting receptive anal sex

- Test for rectal gonorrhea: anal swab culture for *N. gonorrhoeae.*§
- Test for rectal chlamydia: anal swab culture for *C. trachomatis,*§ if available.

For patients reporting receptive oral sex

- Test for pharyngeal gonococcal infection: culture for *N. gonorrhoeae.*§

Subsequent Routine Visits

- The tests described here should be repeated periodically (i.e., at least annually) for all patients who are sexually active. More frequent periodic screening (e.g., at 3-month to 6-month intervals) may be indicated for asymptomatic persons at higher risk. Presence of any of the following factors may support more frequent than annual periodic screening: 1) multiple or anonymous sex partners; 2) past history of any STD; 3) identification of other behaviors associated with transmission of HIV and other STDs; 4) sex or needle-sharing partner(s) with any of the above-mentioned risks; 5) developmental changes in life that may lead to behavioral change with increased risky behaviors (e.g., dissolution of a relationship); or 6) high prevalence of STDs in the area or in the patient population.

* These recommendations apply to persons without symptoms or signs of STDs. Patients with symptoms (e.g., urethral or vaginal discharge; dysuria; intermenstrual bleeding; genital or anal lesions; anal pruritus, burning, or discharge; and lower abdominal pain with or without fever) or known exposure should have appropriate diagnostic testing regardless of reported sexual behavior or other risk factors.

† First-catch urine (i.e., the first 10–30 mL of urine voided after initiating the stream) should be used.

§ The yield of testing for *N. gonorrhoeae* and *C. trachomatis* is likely to vary, and screening for these pathogens should be based on consideration of patient's risk behaviors, local epidemiology of these infections, availability of tests (e.g., culture for *C. trachomatis*), and cost. Appropriate diagnostic tests for different pathogens causing STDs are described (Table 3).

Note: Testing or vaccination for hepatitis, pneumococcal disease, influenza, and other infectious diseases (e.g., screening pregnant women for syphilis, gonorrhea, chlamydia, and hepatitis B surface antigen) should be incorporated into the routine care of HIV-infected persons as recommended elsewhere (*16,21,39,44,54,61–67*).

Note: Symptomatic and asymptomatic herpes simplex virus (HSV) infection, especially with HSV type 2, is prevalent among HIV-infected persons and might increase the risk of transmitting and acquiring HIV. Therefore, some HIV specialists recommend routine, type-specific serologic testing for HSV-2. Patients with positive results should be informed of the increased risk of transmitting HIV and counseled regarding recognition of associated symptoms (*16,54,67*). Only tests for detection of HSV glycoprotein G are truly type-specific and suitable for HSV-2 serologic screening.

Note: Local and state health departments have reporting requirements for HIV and other STDs, which vary among states. Clinicians should be aware of and comply with requirements for the areas in which they practice; information on reporting requirements can be obtained from health departments.

TABLE 3. Available diagnostic testing for detection of sexually transmitted diseases (STDs)*

STD	Diagnostic test†
Syphilis	Dark-field examination or direct fluorescent antibody test of exudate of lesion
	Serum nontreponemal tests, rapid plasma reagin (RPR), or Venereal Disease Research Laboratory (VDRL) for screening followed by serum treponemal tests (e.g., fluorescent treponemal antibody absorbed [FTA-ABS] or *Treponema pallidum* particle agglutination [TP-PA])
Trichonomiasis	Microscopic examination of wet mount or culture of vaginal secretions
Herpes	Viral culture of genital or other mucocutaneous ulcers
	Herpes simplex virus type-specific serologic tests
Gonorrhea	
Female genitourinary [GU] tract	Culture of endocervical swab specimen
	Nucleic acid amplification tests (NAAT) of endocervical swab specimen
	NAAT of urine§
Male GU tract	Culture of intraurethral swab
	NAAT of intraurethral swab
	NAAT of urine§
Rectum/pharynx specimen	Culture of rectal or pharyngeal swab specimen with selective medium
Chlamydia	
Female GU tract	NAAT of endocervical swab specimen
	NAAT of urine§
	Unamplified nucleic acid hybridization test, enzyme immunoassay, or direct fluorescent antibody test of endocervical swab specimen
	Culture of endocervical swab specimen
Male GU tract	NAAT of intraurethral swab specimen
	NAAT of urine§
	Non-NAAT or culture of intraurethral swab specimen
Rectum/pharynx	Culture of rectal or pharyngeal swab specimen¶
	Direct fluorescent antibody test performed on rectal or pharyngeal swab specimen¶

* **Source:** CDC. Sexually transmitted diseases treatment guidelines, 2002. MMWR 2002;51(No. RR-6). CDC Screening tests to detect *Chlamydia trachomatis* and *Neisseria gonorrhoeae* infections—2002. MMWR 2002;51(No. RR-15).
† Diagnostic tests are listed in order of preference for recommendation, with the most highly recommended test listed first. Alternative tests should be performed if a specimen cannot be obtained or if the preferred test is not available.
§ NAAT of urine is less sensitive than that of an endocervical or intraurethral swab specimen.
¶ *Chlamydia trachomatis*-major outer membrane protein (MOMP)–specific stain should be used.

should be tested for pregnancy. Early pregnancy diagnosis would benefit even women not receiving antiretroviral treatment because they could be offered treatment to decrease the risk for perinatal HIV transmission.

Behavioral Interventions

Behavioral interventions are strategies designed to change persons' knowledge, attitudes, behaviors, or practices in order to reduce their personal health risks or their risk of transmitting HIV to others (Table 4). Behavioral change can be facilitated by environmental cues in the clinic or office setting, messages delivered to patients by clinicians or other qualified staff on-site, or referral to other persons or organizations providing prevention services. Because behavior change often occurs in incremental steps, a brief behavioral intervention conducted at each clinic visit could result in patients, over time, adopting and maintaining safer practices. Behavioral interventions should be appropriate for the patient's culture, language, sex, sexual orientation, age, and developmental level (*44*). In settings where care is delivered to HIV-infected adolescents, for example, approaches need to be specifically tailored for this age group (*83*). Also, clinicians should be aware of and adhere to all laws and regulations related to providing services to minors.

Structural Approaches To Support and Enhance Prevention

Clinic or office environments can be structured to support and enhance prevention. All patients, especially new patients, should be provided printed information about HIV transmission risks, preventing transmission of HIV to others, and

TABLE 4. Recommendations for behavioral interventions to reduce human immunodeficiency virus (HIV) transmission risk

Recommendation	Rating
Clinics or office environments where patients with HIV infection receive care should be structured to support and enhance HIV prevention.	B-III (for enhancing patient recall of prevention messages)
Within the context of HIV care, brief general HIV prevention messages should be regularly provided to HIV-infected patients at each visit or periodically, as determined by the clinician, and at a minimum of twice yearly. These messages should emphasize the need for safer behaviors to protect their own health and the health of their sex or needle-sharing partners, regardless of perceived risk. Messages should be tailored to the patient's needs and circumstances.	A-III (for efficacy in promoting safer behaviors)
Patients should have adequate, accurate information regarding factors that influence HIV transmission and methods for reducing the risk for transmission to others, emphasizing that the most effective methods for preventing transmission are those that protect noninfected persons against exposure to HIV (e.g., sexual abstinence; consistent and correct use of condoms made of latex, polyurethane or other synthetic materials; and sex with only a partner of the same HIV status). HIV-infected patients who engage in high-risk sexual practices (i.e., capable of resulting in HIV transmission) with persons of unknown or negative HIV serostatus should be counseled to use condoms consistently and correctly.	A-III (for using brief clinician-delivered messages to influence patient behavior)
Patients' misconceptions regarding HIV transmission and methods for reducing risk for transmission should be identified and corrected. For example, ensure that patients know that 1) per-act estimates of HIV transmission risk for an individual patient vary according to behavioral, biologic, and viral factors; 2) highly active antiretroviral therapy (HAART) cannot be relied upon to eliminate the risk of transmitting HIV to others; and 3) nonoccupational postexposure prophylaxis is of uncertain effectiveness for preventing infection in HIV-exposed partners.	A-III (for using brief clinician-delivered messages to influence patient behavior)
Tailored HIV prevention interventions, using a risk-reduction approach, should be delivered to patients at highest risk for transmitting HIV.	A-III (for efficacy in promoting safer behaviors)
After initial prevention messages are delivered, subsequent longer or more intensive interventions in the clinic or office should be delivered, if feasible.	A-I (for efficacy of multisession, clinic-based interventions in promoting safer behaviors)
HIV-infected patients should be referred to appropriate services for issues related to HIV transmission that cannot be adequately addressed during the clinic visit.	A-I (for efficacy of HIV prevention interventions conducted in nonclinic settings)
Persons who inject illicit drugs should be strongly encouraged to cease injecting and enter into substance abuse treatment programs (e.g., methadone maintenance) and should be provided referrals to such programs.	A-II (for reducing risky drug use and associated sexual behaviors)
Persons who continue to inject drugs should be advised to always use sterile injection equipment and to never reuse or share needles, syringes, or other injection equipment and should be provided information regarding how to obtain new, sterile syringes and needles (e.g., syringe exchange program).	A-II (for reducing risk for HIV transmission)

preventing acquisition of other STDs. Information can be disseminated at various locations in the clinic; for example, posters and other visual cues containing prevention messages can be displayed in examination rooms and waiting rooms. These materials usually can be obtained through local or state health department HIV/AIDS and STD programs or from the National Prevention Information Network (NPIN) (1-800-458-5231; http://www.cdcnpin.org). Additionally, condoms should be readily accessible at the clinic. Repeating prevention messages throughout the patient's clinic visit reinforces their importance, increasing the likelihood that they will be remembered (*68*).

Interventions Delivered On-Site

Prevention Messages for All Patients

All HIV-infected patients can benefit from brief prevention messages emphasizing the need for safer behaviors to protect both their own health and the health of their sex or needle-sharing partners. These messages can be delivered by clinicians, nurses, social workers, case managers, or health educators. They include discussion of the patient's responsibility for appropriate disclosure of HIV serostatus to sex and needle-sharing partners. Brief clinician-delivered approaches have been effective with a variety of health issues, including depression (*84*), smoking (*85–90*), alcohol abuse (*91,92*), weight and diet (*93*), and physical inactivity (*94*). This diverse experience with other health behaviors suggests that similar approaches may be effective in reducing HIV-infected patients' transmission risk behaviors. For patients already taking steps to reduce their risk of transmitting HIV, hearing the messages can reinforce continued risk-reduction behaviors. These patients should be commended and encouraged to continue these behaviors.

General HIV Prevention Messages

Patients frequently have inadequate information regarding factors that influence HIV transmission and methods for

preventing transmission. The clinician should ensure that patients understand that the most effective methods for preventing HIV transmission remain those that protect noninfected persons against exposure to HIV. For sexual transmission, the only certain means for HIV-infected persons to prevent sexual transmission to noninfected persons are sexual abstinence or sex with only a partner known to be already infected with HIV. However, restricting sex to partners of the same serostatus does not protect against transmission of other STDs or the possibility of HIV superinfection unless condoms of latex, polyurethane, or other synthetic materials are consistently and correctly used. Superinfection with HIV has been reported and appears to be rare, but its clinical consequences are not known (*95,96*). For injection-related transmission, the only certain means for HIV-infected persons to prevent transmission to noninfected persons are abstaining from injection drug use or, for IDUs who are unable or unwilling to stop injecting drugs, refraining from sharing injection equipment (e.g., syringes, needles, cookers, cottons, water) with other persons. Neither antiretroviral therapy for HIV-infected persons nor postexposure prophylaxis for partners is a reliable substitute for adopting and maintaining behaviors that guard against HIV exposure (*97*).

Identifying and Correcting Misconceptions

Patients might have misconceptions about HIV transmission (*98*), particularly with regard to the risk for HIV transmission associated with specific behaviors, the effect of antiretroviral therapy on HIV transmission, or the effectiveness of postexposure prophylaxis for nonoccupational exposure to HIV.

Risk for HIV Transmission Associated with Specific Sexual Behaviors. Patients often ask their clinicians about the degree of HIV transmission risk associated with specific sexual activities. Numerous studies have examined the risk for HIV transmission associated with various sex acts (*99–113*). These studies indicate that some sexual behaviors do have a lower average per-act risk for transmission than others and that replacing a higher-risk behavior with a relatively lower-risk behavior might reduce the likelihood that HIV transmission will occur. However, risk for HIV transmission is affected by numerous biological factors (e.g., host genetics, stage of infection, viral load, coexisting STDs) and behavioral factors (e.g., patterns of sexual and drug-injection partnering) (*105,114*), and per-act risk estimates based on models that assume a constant per-contact infectivity could be inaccurate (*110,113*). Thus, estimates of the absolute per-episode risk for transmission associated with different activities could be highly misleading when applied to a specific patient or situation. Further the relative risks of becoming infected with HIV, from the perspective of a person not infected with HIV, might vary greatly according to the various choices related to sexual behavior (Table 5) (*115,116*).

Effect of Antiretroviral Therapy on HIV Transmission. High viral load is a major risk factor for HIV transmission (*117–125*). Among untreated patients, the risk for HIV transmission through heterosexual contact has been shown to increase approximately 2.5-fold for each 10-fold increase in plasma viral load (126) (Table 6). By lowering viral load, antiretroviral therapy might reduce risk for HIV transmission, as has been demonstrated with perinatal transmission (*127,128*) and indirectly suggested for transmission via genital secretions (semen and cervicovaginal fluid) (*2,129–133*). However, because HIV can be detected in the semen, rectal secretions, female genital secretions, and pharynx of HIV-infected patients with undetectable plasma viral loads (*16,134–137*) and because consistent reduction of viral load depends on high

TABLE 5. Estimated per-act relative risk for a person without human immunodeficiency virus (HIV) infection acquiring HIV infection, based on sex act* and condom use†

Risk factor	Relative risk for a person without HIV infection of acquiring HIV infection
Sex act	
Insertive fellatio§	1
Receptive fellatio§	2
Insertive vaginal sex¶	10
Receptive vaginal sex¶	20
Insertive anal sex¶	13
Receptive anal sex¶	100
Condom use	
Yes**	1
No**	20

Note: This table quantifies the relative risk for HIV transmission in a way that can help compare the effects of a person's choices of sex act and condom use. It is presented from the point of view of a person without HIV infection and should be used to educate the HIV-infected patient regarding risks for transmission to partners who are not HIV infected or have unknown HIV serostatus. These risks are estimated from available data. Risks can vary depending on several factors, including presence of STDs in either partner and the HIV-infected partner's viral load. In addition, the relative frequency of performance of higher- and lower-risk sex acts will affect risk for transmission (see Prevention Messages for All Patients).

Note: The risks of these choices are multiplicative. Compared with the lowest relative risk (performing insertive fellatio using a condom; referent group, RR = 1), the overall relative risk increases to 2,000 when performing receptive anal sex (RR = 100) without a condom (RR = 20).

* Data regarding risk for transmission from sharing drug injection equipment are too limited to be included in this table.

TABLE 6. Adjusted rate ratios of the risk for transmission and acquisition of human immunodeficiency virus type 1 (HIV-1) among discordant partners*

Serum viral load of HIV-infected partners (copies/mL)†	Risk for transmission to partners not infected with HIV (adjusted rate ratio; 95% confidence interval)
<3500	Referent
3500–9999	5.80 (2.26–17.80)
10,000–49,999	6.91 (2.96–20.15)
>50,000	11.87 (5.02–34.88)
Per log increment viral load	2.45 (1.85–3.26)

* **Source:** Quinn TC, Wawer MJ Sewankambo N, et al. Viral load and heterosexual transmission of human immunodeficiency virus type 1 from mother to infant. N Engl J Med 1996;335:1621–9.

† Patients in this study did not receive antiretroviral medications, and those with low viral loads might have been long-term nonprogressors. Risks might not be equivalent for treated persons with low viral loads.Viral load in the blood may not be predictive of viral load in the genital tract; therefore, risks may vary with genital tract viral load.

adherence to antiretroviral regimens, the clinician should assume that all patients who are receiving therapy, even those with undetectable plasma HIV levels, can still transmit HIV. Patients who have treatment interruptions, whether scheduled or not, should be advised that this will likely lead to a rise in plasma viral load and increased risk for transmission. Another concern related to adherence to antiretroviral therapy is the development of drug-resistant mutations with subsequent transmission of drug-resistant viral strains. Several reports suggest that transmission of drug-resistant HIV occurs in the United States (*138–141*). Recent reports suggest that drug-resistant HIV strains might be less easily transmitted than wild-type virus (*142*), but these data are limited and their significance is unclear.

Effectiveness of Postexposure Prophylaxis for Non occupational Exposure to HIV. Although the U.S. Public Health Service recommends using antiretroviral drugs to reduce the likelihood of acquiring HIV infection from occupational exposure (e.g., accidental needle sticks received by health care workers) (*143*), limited data are available on efficacy of prophylaxis for nonoccupational exposure (*97,143–147*). Observational data suggesting effectiveness have been reported (*148*); however, postexposure prophylaxis might not protect against infection in all cases, and effectiveness of these regimens might be further hindered by lack of tolerability, potential toxicity, or viral resistance. Thus, avoiding exposure remains the best approach to preventing transmission, and the potential availability of postexposure prophylaxis should not be used as justification for engaging in risky behavior.

Tailored Interventions for Patients at High Risk for Transmitting HIV

Interventions tailored to the individual patient's risks can be delivered to patients at highest risk for transmitting HIV infection and for acquiring new STDs. This includes patients whose risk screening indicates current sex or drug-injection practices that may lead to transmission, who have a current or recent STD, or who have mentioned items of concern in discussions with the clinician (*149,150*). Any positive results of screening for behavioral risks or STDs should be addressed in more detail with the patient so a more thorough risk assessment can be done and an appropriate risk-reduction plan can be discussed and agreed upon.

Although the efficacy of brief clinician-delivered interventions with HIV-infected patients has not been studied extensively, substantial evidence exists for the efficacy of provider-delivered, tailored messages for other health concerns (*151–155*). An attempt should be made to determine which of the patient's risk behaviors and underlying concerns can be addressed during clinic visits and which might require referral (Box 3).

At a minimum, an appropriate referral should be made and the patient should be informed of the risks involved in continuing the behavior. HIV-infected persons who remain sexually active should be reminded that the only certain means for preventing transmission to noninfected persons is to restrict sex to partners known to be already infected with HIV and that they have a responsibility for disclosure of HIV serostatus to prospective sex partners. For mutually consensual sex with a person of unknown or discordant HIV serostatus, consistent and correct use of condoms made of latex, polyurethane, or other synthetic materials can substantially reduce the risk for HIV transmission. Also, some sex acts have relatively less risk for HIV transmission than others (Table 5). For HIV-infected patients who continue injection drug use, the provider should emphasize the risks associated with sharing needles and should provide information regarding substance abuse treatment and access to clean needles (Box 4) (*156–158*). Examples of targeted motivational messages on condom use and needle sharing are provided (Figures 1 and 2), and providers can individualize their own messages using these as a guide.

Clinician Training

Clinicians can prepare themselves to deliver HIV prevention messages and brief behavioral interventions to their patients by 1) developing strategies for incorporating HIV risk-reduction interventions into patients' clinic visits (*159*); 2) obtaining training on speaking with patients about sex and drug-use behaviors and on giving explanations in simple, everyday language (*68,87,160,161*); 3) becoming familiar with interventions that have demonstrated effectiveness (*162*); 4) becoming familiar with the underlying causes of and concerns related to risk behaviors among HIV-infected persons

BOX 3. Examples of which concerns to address and which to refer

Topics that can be successfully addressed by clinicians and clinic support staff:

- lack of knowledge about HIV transmission risks;
- misconceptions about risk of specific types of sexual and drug-use practices;
- misconceptions about viral load and transmission of HIV;
- how to disclose HIV-seropositive status to a sex partner, family member, or friend;
- importance of using condoms or not exchanging fluids with partners;
- ways to reduce number of sex or drug partners;
- ways to keep condoms accessible;
- ways to remember to use condoms;
- how to persuade a sex partner to use a condom;
- ways to obtain support (e.g., emotional, financial) from family, friends, and lovers;
- ways to clean/disinfect injection equipment;
- ways to obtain clean needles;
- ways to avoid sharing injection equipment; or
- ways to deal with mild psychological distress stemming from situational circumstances.

Issues that might need referral to outside agencies

- need for intensive HIV prevention intervention;
- excessive use of alcohol or recreational drug use;
- drug addiction, including injection drug use;
- depression, anger, guilt, fear, or other mental health needs;
- need for social support;
- sexual compulsivity;
- sexual or physical abuse (victim or perpetrator);
- desire to have children, contraceptive counseling;
- housing or transportation needs;
- nutritional needs;
- financial emergencies;
- child custody, parole, or other legal matters; or
- insurance coverage.

(e.g., domestic violence) (*13,163*); and 5) becoming familiar with community resources that address risk reduction. Free training on risk screening and prevention can be obtained at CDC-funded STD/HIV Prevention Training Centers (http://depts.washington.edu/nnptc) and HRSA-funded AIDS Education and Training Centers (http://www.aids-ed.org), which also offer continuing medical education credit for this training. Ongoing training will help clinicians refine their counseling skills as well as keep current with prevention concerns at the community level, thus increasing their ability to appropriately counsel and provide support to patients.

BOX 4. Examples of messages that should be communicated to drug users who continue to inject*

Persons who inject drugs should be regularly counseled to do the following:

- Stop using and injecting drugs.
- Enter and complete substance abuse treatment, including relapse prevention.
- Take the following steps to reduce personal and public health risks, if they continue to inject drugs:
  - — Never reuse or share syringes, water, or drug preparation equipment.
  - — Use only syringes obtained from a reliable source (e.g., pharmacies).
  - — Use a new, sterile syringe to prepare and inject drugs.†
  - — If possible, use sterile water to prepare drugs; otherwise, use clean water from a reliable source (such as fresh tap water).
  - — Use a new or disinfected container (cooker) and a new filter (cotton) to prepare drugs.
  - — Clean the injection site with a new alcohol swab before injection.
  - — Safely dispose of syringes after one use.

In addition, drug users should be provided information regarding how to prevent HIV transmission through sexual contact and, for women, information regarding reducing the risk of mother-to-infant HIV transmission.

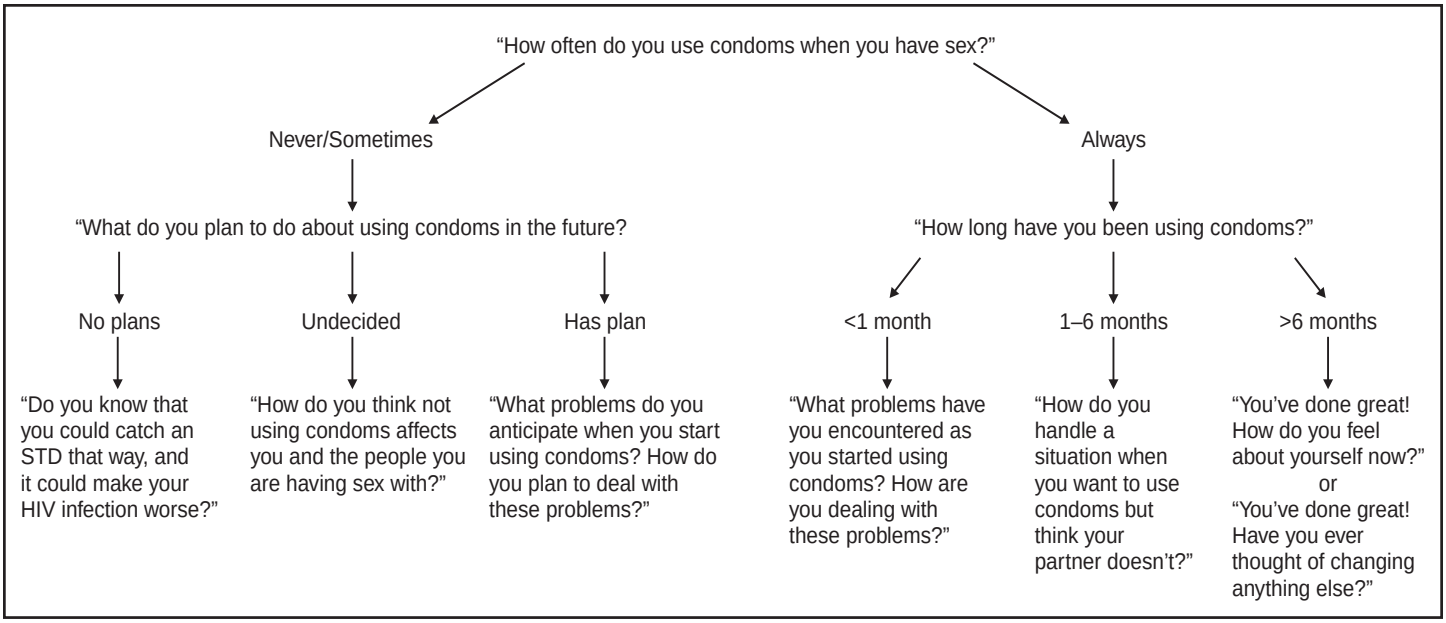
* **Source:** US Department of Health and Human Services. Medical advice for persons who inject illicit drugs. HIV Prevention Bulletin. CDC; Health Resources and Services Administration; National Institute on Drug Abuse, National Institutes of Health; Center for Substance Abuse and Mental Health Services Administration. May 1997. Available at http://www.cdc.gov/idu/pubs/hiv_prev.htm.

† If new, sterile syringes and other drug preparation and injection equipment are not available, previously used equipment should be boiled or disinfected with bleach by using the methods recommended by CDC (**Source:** CDC National Prevention Information Network. HIV connect. Vol. 11, No.8. Available at http://www.cdcnpin.org).

Ongoing Delivery of Prevention Messages

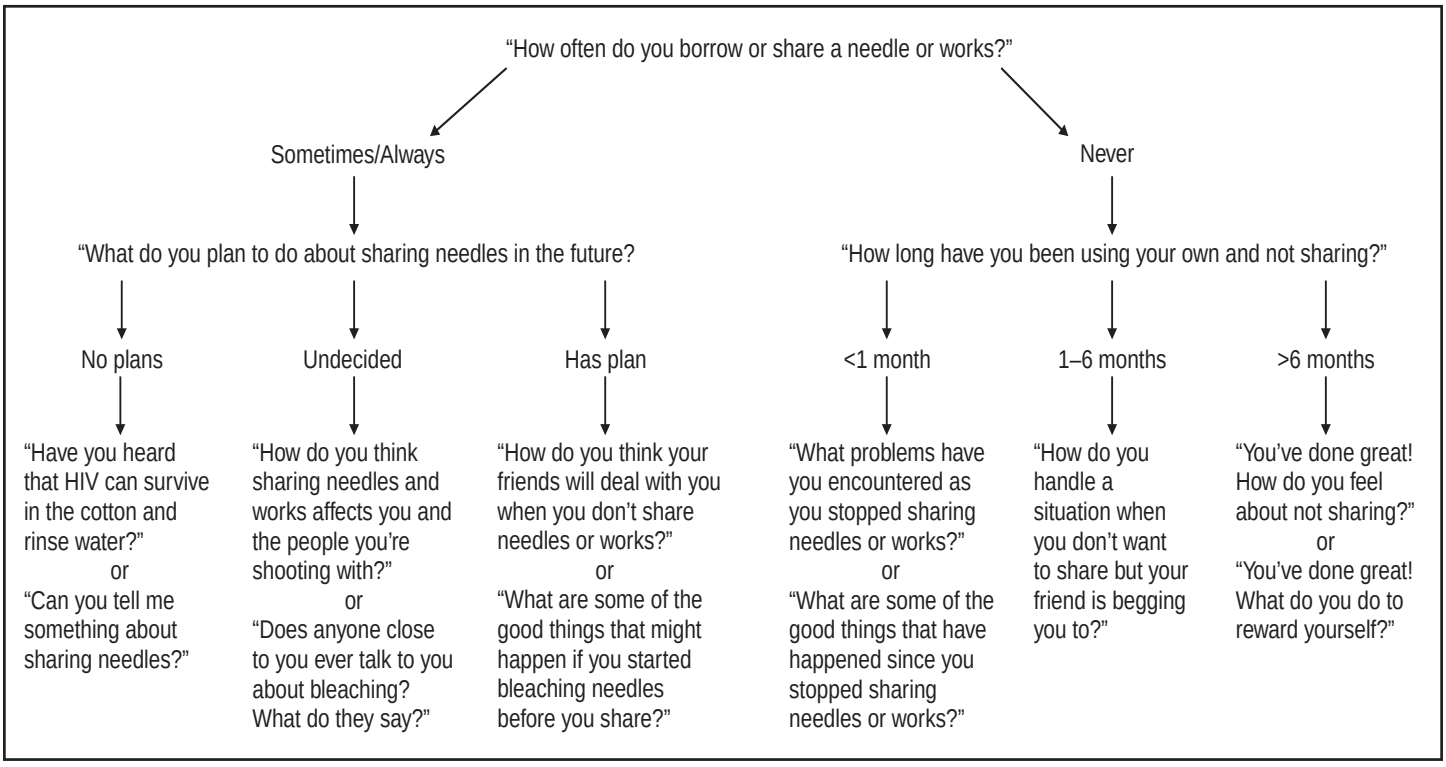
Prevention messages can be reinforced by subsequent longer or more intensive interventions in clinic or office environments by nurses, social workers, or health educators. Advantages of a multidisciplinary approach are that skill sets vary among staff members from various disciplines and that a patient may be more receptive to discussing prevention-related issues with one team member than with another. For HIV-negative persons or persons of unknown HIV serostatus, randomized controlled trials provide strong evidence for the efficacy of short, one- or two-session interventions (*164–170*) and for longer or multisession interventions in clinics for individuals and groups (*164,171–173*). For example, for persons who continue to engage in risky behaviors, CDC recommends client-centered counseling, a specific model of HIV prevention counseling

FIGURE 1. Example of tailoring messages regarding condom use for sexually active, HIV-infected persons



* This is an example, not a comprehensive list of all questions that could be asked

FIGURE 2. Example of tailoring messages regarding needle sharing for HIV-infected persons who continue to inject drugs



* This is an example, not a comprehensive list of all questions that could be asked

(*44,164*). Evidence for the efficacy of multisession interventions for HIV-infected patients, individually or in groups, in clinical settings is limited to a few randomized, controlled trials (*69,174,175*) and other studies that might not have assessed behavioral outcomes (*6,176–180*). The studies of single-session interventions for individual HIV-infected patients in clinical settings have not been randomized controlled trials (*181–187*).

Referrals for Additional Prevention Interventions and Other Services

Types of Referrals

Certain patients need more intensive or ongoing behavioral interventions than can feasibly be provided in medical care settings (*44*). Many have underlying problems that impede adoption of safer behaviors (e.g., homelessness, substance abuse, mental illness), and achieving behavioral change is often dependent on addressing these concerns. Clinicians will usually not have time or resources to fully address these issues, many of which can best be addressed through referrals for services such as intensive HIV prevention interventions (e.g., multisession risk-reduction counseling, support groups), medical services (e.g., family planning and contraceptive counseling, substance abuse treatment), mental health services (e.g., treatment of depression, counseling for sexual compulsivity), and social services (e.g., housing, child care and custody, protection from domestic violence). For example, all patients should be made aware of their responsibility for appropriate disclosure of HIV serostatus to sex and needle-sharing partners; however, full consideration of the complexities of disclosure, including benefits and potential risks, may not be possible in the time available during medical visits (*188*). Patients who are having, or are likely to have, difficulty initiating or sustaining behaviors that reduce or prevent HIV transmission might benefit from prevention case management. Prevention case management provides ongoing, intensive, one-on-one, client-centered risk assessment and prevention counseling, and assistance accessing other services to address concerns that affect patients' health and ability to change HIV-related risk-taking behavior. For HIV-seronegative persons, randomized controlled trials provide evidence for the efficacy of HIV prevention interventions delivered by health departments and community-based organizations (*164,189–198*). For HIV-infected persons, efficacy studies of such interventions are limited to a few randomized controlled trials (*199–201*), only one of which documented change in risk-related behavior (*199*), and to other studies, the majority of which did not assess behavioral outcomes (*7,202–207*).

Referrals for IDUs

For IDUs, ceasing injection-drug use is the only reliable way to eliminate the risk of injection-associated HIV transmission; however, most IDUs are unable to sustain long-term abstinence without substance abuse treatment. Several studies have examined the effect of substance abuse treatment, particularly methadone maintenance treatment, on HIV risk behaviors among IDUs (*208–210*). These include controlled (*211–217*) and noncontrolled (*218–221*) cohort studies, case-control studies (*222*), and observational studies with controls (*223,224*), and collectively they provide evidence that methadone maintenance treatment reduces risky injection and sexual behaviors and HIV seroconversion. Thus, early entry into substance abuse treatment programs, maintenance of treatment, and sustained abstinence from injecting are crucial for reducing the risk for HIV transmission from infected IDUs. For those IDUs not able or willing to stop injecting drugs, once-only use of sterile syringes can greatly reduce the risk for injection-related HIV transmission. Substantial evidence from cohort, case-control, and observational studies (*225*) indicates that access to sterile syringes through syringe exchange programs reduces HIV risk behavior and HIV seroconversion among IDUs. Physician prescribing and pharmacy programs can also increase access to sterile syringes (*226–231*). Disinfecting syringes and other injection equipment by boiling or flushing with bleach when new, sterile equipment is not available has been suggested to reduce the risk for HIV transmission (*156*); however, it is difficult to reliably disinfect syringes, and this practice is not as safe as using a new, sterile syringe (*232–234*). Information on access to sterile syringes and safe syringe disposal can be obtained through local health departments or state HIV/AIDS prevention programs.

Engaging the Patient in the Referral Process

When referrals are made, the patient's willingness and ability to accept and complete a referral should be assessed. Referrals that match the patient's self-identified priorities are more likely to be successful than those that do not; the services need to be responsive to the patient's needs and appropriate for the patient's culture, language, sex, sexual orientation, age, and developmental level. For example, adolescents should be referred to behavioral intervention programs and services that work specifically with this population. Discussion with the patient can identify barriers to the patient's completing the referral (e.g., lack of transportation or child care, work schedule, cost). Accessibility and convenience of services predict whether a referral will be completed. The patient should be given specific information regarding accessing referral services and might need assistance (e.g., scheduling appointments, obtaining transportation) in completing referrals. The likelihood that

referrals will be completed successfully could possibly be increased if clinicians or other health-care staff assist patients with making appointments to referral services. When a clinician does not have the capacity to make all appropriate referrals, or when needs are especially complex, a case manager can help make referrals and coordinate care. Outreach workers, peer counselors or educators, treatment advocates, and treatment educators can also help patients identify needs and complete referrals successfully. Health department HIV/AIDS prevention and care programs can provide information on accessing these services. Assessing the success of referrals by documenting referrals made, the status of those referrals, and patient satisfaction with referrals will further assist clinicians in meeting patient needs. Information obtained through follow-up of referrals can identify barriers to completing the referral, responsiveness of referral services to patient needs, and gaps in the referral system, and can be used to develop strategies for removing the barriers.

Referral Guides and Information

Preparation for making patient referrals includes 1) learning about local HIV prevention and supportive social services, including those supported by the Ryan White CARE Act; 2) learning about available resources and having a referral guide listing such resources; and 3) contacting staff in local programs to facilitate subsequent referrals. Referral guides and other information usually can be obtained from local and state health department HIV/AIDS prevention and care programs, which are key sources of information about services available locally. Health departments and some managed care organizations are also a source of educational materials, posters, and other prevention-related material. Health departments can provide or suggest sources of training and technical assistance on behavioral interventions. A complete listing of state AIDS directors and contact information is available from the National Alliance of State and Territorial AIDS Directors (NASTAD) at http://www.nastad.org. In addition, information can be obtained from local health planning councils, consortia, and community planning groups; local, state, and national HIV/AIDS information hotlines and Internet websites; and community-based health and human service providers (Box 5).

BOX 5. Referral resource guide, suggested contents

For each resource, the referral resource guide should specify

- name of the provider or agency;
- range of services provided;
- target population(s);
- service area(s);
- contact names and telephone and fax numbers, street addresses, e-mail addresses;
- hours of operation;
- location;
- competence in providing services appropriate to the patient's culture, language, sex, sexual orientation, age, and developmental level;
- cost for services;
- eligibility;
- application materials;
- admission policies and procedures;
- directions, transportation information, and accessibility to public transportation; and
- patient satisfaction with services.

Examples of Case Situations for Prevention Counseling

1. A patient with newly diagnosed HIV infection comes to your office for initial evaluation. Of the many things that must be addressed during this initial visit (e.g., any emergent medical or psychiatric problems, education about HIV, history, physical, initial laboratory work [if not already done]), how does one address prevention? What is the minimum that should be done, and how can it be incorporated into this visit?

Assuming no emergent issues preclude a complete history and physical examination during this visit, the following should be done:

- During the history, question how the patient might have acquired HIV, current risk behaviors, current partners and whether they have been notified and tested for HIV, and current or past STDs.
- During the physical examination, include genital and rectal examinations, evaluation and treatment of any current STD, or, if asymptomatic, appropriate screening for STDs.
- Discuss current risk behavior, at least briefly. Emphasize the importance of using condoms; address active injection-drug use.
- Discuss the need for disclosure of HIV serostatus to sex and needle-sharing partners, and discuss potential barriers to disclosure.
- Note issues that will require follow-up; e.g., risk behavior that will require continuing counseling and referral and partners who will need to be notified by either the patient or a health department.

2. A patient with chronic, stable HIV comes to you with a new STD. What prevention considerations should be covered in this visit?

For the patient who has had a stable course of disease, a new STD can be a sign of emerging social, emotional, or substance

abuse problems. These potential problems should be addressed in addition to the STD.

- During the history, cover topics related to acquisition of the new STD—number of new partners, number of episodes of unsafe sex, and types of unsafe sex.
- Address the personal risks associated with high-risk behavior, e.g., viral superinfection and HIV/STD interactions.
- Address personal or social problems (including substance abuse and domestic violence) that might have led to a change in behavior resulting in the acquisition of the new STD; refer to social services, if necessary.
- Address other issues (e.g., adherence to HAART) that may be affected by personal or social problems. Check viral load if nonadherence is evident or is suspected.
- During the physical examination, include a careful genital and rectal examination and screen for additional STDs, such as syphilis, trichomoniasis, (for women), chlamydial infection (for sexually active women aged ≤25 years and selected populations of men and women), and gonorrhea (for selected populations of men and women).
- Discuss the need for partner notification and referral for counseling and testing.
- Note in the chart that risk behavior should be addressed in future visits and that tailored counseling may be needed for the patient.

3. A patient with chronic, stable HIV has been seen regularly in a health care setting. What should be included in this patient's routine clinical care?

Discussion of sexual and needle-sharing practices should be integrated into a routine part of clinical care.

- Periodically (e.g., annually) screen for STDs. STDs to be included in screening should be determined by patient's sex, history of high-risk behavior, and local epidemiology of selected STDs.
- Reiterate general prevention messages and patient education regarding partner notification, high-risk behaviors associated with transmission, prevention of transmission, or condom use, as deemed appropriate by the clinician.

4. A patient who has been treated with HAART for 2 years comes to you. At the time of treatment initiation, CD4$^+$count was 200 cells/µL and the viral load was 50,000 copies/ml. The response to therapy was prompt; CD4$^+$ count increased to 500 cells/µL, and the viral load has been undetectable since soon after treatment began. The patient now has mildly elevated cholesterol, some mild lipodystrophy, and facial wasting. He states that he would like to stop HAART because of the side effects. What should you tell this patient?

- Inform the patient that upon stopping HAART, CD4$^+$ count and viral load will likely return to pretreatment levels with risk for opportunistic infections and progression of immune deficiency.
- Inform the patient that increase in viral load to pretreatment levels will likely result in increased infectiousness and risk for transmission of HIV to sex or needle-sharing partners.
- Counsel the patient regarding the option of changing the HAART regimen to limit progression of metabolic side effects.

Partner Counseling and Referral Services, Including Partner Notification

HIV-infected persons are often not yet aware of their infection; thus, they cannot benefit from early medical evaluation and treatment and do not know that they may be transmitting HIV to others. Reaching such persons as early after infection as possible is important for their own health and is a critical strategy for reducing HIV transmission in the community. Furthermore, interviews of HIV-infected persons in various settings suggest that >70% are sexually active after receiving their diagnosis, and many have not told their partners about their infection (*188*). Partner counseling and referral services (PCRS), including partner notification, are intended to address these problems by 1) providing services to HIV-infected persons and their sex and needle-sharing partners so the partners can take steps to avoid becoming infected or, if already infected, to avoid infecting others and 2) helping infected partners gain earlier access to medical evaluation, treatment, and other services (Table 7). A key element of PCRS involves informing current partners (and past partners who may have been exposed) that a person who is HIV infected has identified them as a sex or needle-sharing partner and advising them to have HIV counseling and testing (*235–238*).

Informing partners of their exposure to HIV is confidential; i.e., partners are not told who reported their name or when the reported exposure occurred. It is voluntary in that the infected person decides which names to reveal to the interviewer. Studies have indicated that infected persons are more likely to name their close partners than their more casual partners (*204,239,240*). Limited reports of partner violence after notification suggest a need for caution, but such violence seems to be rare (*241–2*). When asked, 92% of notified partners reported that they believe the health department should continue partner notification services (*243*). No studies have directly shown that PCRS prevents disease in a community.

TABLE 7. Recommendations for partner counseling and referral, including partner notification

Recommendation	Rating
In HIV health-care settings, all applicable requirements for reporting sex and needle-sharing partners of HIV-infected patients to the appropriate health department should be followed.	A-III (for identifying patients who should be referred for partner counseling and referral services [PCRS])
At the initial visit, patients should be asked if all of their sex and needle-sharing partners have been informed of their exposure to HIV.	A-III (for identifying patients who should be referred for PCRS)
At routine follow-up visits, patients should be asked if they have had any new sex or needle-sharing partners who have not been informed of their exposure to HIV.	A-III (for identifying patients who should be referred for PCRS)
All patients should be referred to the appropriate health department to discuss sex and needle-sharing partners who have not been informed of their exposure and to arrange for their notification and referral for HIV testing.	A-I (for increasing partner counseling and referral and voluntary testing of partners)
In HIV health-care settings, access to available community partner counseling and referral resources should be established.	A-III (for establishing a working relationship and increasing understanding about partner counseling and referral procedures)

However, studies have demonstrated that quality HIV prevention counseling can reduce the risk of acquiring a new STD (*164*) and that persons who become aware of their HIV infection can take steps to protect their health and prevent further transmission *(244)*; in addition, before–after studies have suggested that partners change their behavior after they are notified (*245*). Finally, compelling arguments have been offered regarding partners' rights to know this information that is important to their health.

Laws and Regulations Related to Informing Partners

The majority of states and some cities or localities have laws and regulations related to informing partners that they have been exposed to HIV. Certain health departments require that, even if a patient refuses to report a partner, the clinician report to the health department any partner of whom he or she is aware. Many states also have laws regarding disclosure by clinicians to third parties known to be at high risk for future HIV transmission from patients known to be infected (i.e., duty to warn) (*246*). Clinicians should know and comply with any such requirements in the areas in which they practice. With regard to PCRS, clinicians should also be aware of and adhere to all laws and regulations related to providing services to minors.

Approaches to Notifying Partners

Partners can be reached and informed of their exposure by health department staff, clinicians in the private sector, or the infected person. In the only randomized controlled trial that has been conducted to date (*175*), 35 HIV-infected persons were asked to notify their partners themselves, and 10 partners were notified. Another 39 HIV-infected persons were assigned to health department referral; and for these, 78 partners were notified. Thus, notification by the health department appears to be substantially more effective than notification by the infected person. Other studies, with less rigorous designs, have demonstrated similar results (*247,248*). Some persons, when asked, prefer to inform their partners themselves. This could have a benefit if partners provide support to the infected person. However, patients frequently find that informing their partners is more difficult than they anticipated. Certain health departments offer contract referral, in which the infected person has a few days to notify his or her partners. If by the contract date the partners have not had a visit for counseling and testing, they are then contacted by the health department. In practice, patients' difficulties in informing their partners usually means notification is done by the health department.

Although clinicians might wish to take on the responsibility for informing partners, one observational study has indicated that health department specialists were more successful than physicians in interviewing patients and locating partners (*249*). Health departments have staff who are trained to do partner notification and skilled at providing this free, confidential service. These disease intervention specialists can work closely with public and private sector clinicians who treat persons with other STDs. With regard to partner notification, the clinician should be sensitive to concerns of domestic violence or abuse by the informed partner.

All partners should be notified at least once. Persons who continue to have sex with an HIV-infected person despite an earlier notification may have erroneously concluded that someone else was the infected partner. Thus, renotification might be important, although no research is available on renotification.

Additional information, recommendations, and requirements related to PCRS are available through health department HIV/AIDS programs. A complete listing of state AIDS directors and contact information is available from the National Alliance of State and Territorial AIDS Directors (NASTAD) at http://www.nastad.org.

Acknowledgments

The preparers are grateful to P. Lynne Stockton, V.M.D, and P. Susanne Justice, CDC, for their editorial assistance and to Mark R. Vogel, M.A., HIVMA of IDSA, who assisted in coordinating responses from members of that organization.

Summary of recommendations for human immunodeficiency virus (HIV) prevention among HIV-infected persons in clinical care settings

Recommendation	Rating*
HIV-infected patients should be screened for behaviors associated with HIV transmission by using a straightforward, nonjudgmental approach. This should be done at the initial visit and subsequent routine visits or periodically, as the clinician feels necessary, but at a minimum of yearly. Any indication of risky behavior should prompt a more thorough assessment of HIV transmission risks.	A-II
At the initial and each subsequent routine visit, HIV-infected patients should be questioned about symptoms of sexually transmitted diseases (STDs) (e.g., urethral or vaginal discharge; dysuria; intermenstrual bleeding; genital or anal ulcers; anal pruritus, burning, or discharge; and, for women, lower abdominal pain with or without fever). Regardless of reported sexual behavior or other epidemiologic risk information, the presence of such signs or symptoms should always prompt diagnostic testing and, when appropriate, treatment.	A-I
At the initial visit • All HIV-infected women and men should be screened for laboratory evidence of syphilis. Women should also be screened for trichomoniasis. Sexually active women aged ≤25 years and other women at increased risk, even if asymptomatic, should be screened for cervical chlamydial infection.	A-II
• Consideration should be given to screening all HIV-infected men and women for gonorrhea and chlamydial infections. However, because of the cost of screening and the variability of prevalence of these infections, decisions about routine screening for these infections should be based on epidemiologic factors (including prevalence of infection in the community or the population being served), availability of tests, and cost. (Some HIV specialists also recommend type-specific serologic testing for herpes simplex virus type 2 for both men and women.)	B-II
Screening for STDs should be repeated periodically (i.e., at least annually) if the patient is sexually active or if earlier screening revealed STDs. Screening should be done more frequently (e.g., at 3–6-month intervals) for asymptomatic persons at higher risk.	B-III
At the initial and each subsequent routine visit, HIV-infected women of childbearing age should be questioned to identify possible current pregnancy, interest in future pregnancy, or sexual activity without reliable contraception. They should be referred for appropriate counseling, reproductive health care, or prenatal care, as indicated. Women should be asked whether they suspect pregnancy or have missed their menses and, if so, should be tested for pregnancy.	A-I
Clinics or office environments where patients with HIV infection receive care should be structured to support and enhance HIV prevention.	B-III
Within the context of HIV care, brief general HIV prevention messages should be regularly provided to HIV-infected patients at each visit, or periodically, as determined by the clinician, and at a minimum of twice yearly. These messages should emphasize the need for safer behaviors to protect their own health and the health of their sex or needle-sharing partners, regardless of perceived risk. Messages should be tailored to the patient's needs and circumstances.	A-III
Patients should have adequate, accurate information regarding factors that influence HIV transmission and methods for reducing the risk for transmission to others, emphasizing that the most effective methods for preventing transmission are those that protect noninfected persons against exposure to HIV (e.g., sexual abstinence; consistent and correct use of condoms made of latex, polyurethane or other synthetic materials; and sex with only a partner of the same HIV serostatus). HIV-infected patients who engage in high-risk sexual practices (i.e., capable of resulting in HIV transmission) with persons of unknown or negative HIV serostatus should be counseled to use condoms consistently and correctly.	A-III
Patients' misconceptions regarding HIV transmission and methods for reducing risk for transmission should be identified and corrected. For example, ensure that patients know that 1) per-act estimates of HIV transmission risk for an individual patient vary according to behavioral, biologic, and viral factors; 2) highly active antiretroviral therapy (HAART) cannot be relied upon to eliminate the risk of transmitting HIV to others; and 3) nonoccupational postexposure prophylaxis is of uncertain effectiveness for preventing infection in HIV-exposed partners.	A-III
Tailored HIV prevention interventions, using a risk-reduction approach, should be delivered to patients at highest risk for transmitting HIV.	A-III
After initial prevention messages are delivered, subsequent longer or more intensive interventions in the clinic or office should be delivered, if feasible.	A-I
HIV-infected patients should be referred to appropriate services for issues related to HIV transmission that cannot be adequately addressed during the clinic visit.	A-I
Persons who inject illicit drugs should be strongly encouraged to cease injecting and enter into substance abuse treatment programs (e.g., methadone maintenance) and should be provided referrals to such programs.	A-II
Persons who continue to inject drugs should be advised to always use sterile injection equipment and to never reuse or share needles, syringes, or other injection equipment and should be provided information regarding how to obtain new, sterile syringes and needles (e.g., syringe exchange programs).	A-II
In HIV health-care settings, all applicable requirements for reporting sex and needle-sharing partners of HIV-infected patients to the appropriate health department should be followed.	A-III
At the initial visit, patients should be asked if all of their sex and needle-sharing partners have been informed of their exposure to HIV.	A-III
At routine follow-up visits, patients should be asked if they have had any new sex or needle-sharing partners who have not been informed of their exposure to HIV.	A-III
All patients should be referred to the appropriate health department to discuss sex and needle-sharing partners who have not been informed of their exposure and to arrange for their notification and referral for HIV testing.	A-I
In HIV health-care settings, access to available community partner counseling and referral resources should be established.	A-III

* Letters indicate the strength of the recommendation, and roman numerals indicate the quality of evidence supporting it, respectively (see Table 1).

MMWR™

Morbidity and Mortality Weekly Report

Recommendations and Reports July 18, 2003 / Vol. 52 / No. RR-12

Continuing Education Activity Sponsored by CDC
Incorporating HIV Prevention into the Medical Care of Persons Living with HIV
Recommendations of CDC, the Health Resources and Services Administration, the National Institutes of Health, and the HIV Medicine Association of the Infectious Diseases Society of America

EXPIRATION — July 18, 2006

You must complete and return the response form electronically or by mail by **July 18, 2006**, to receive continuing education credit. If you answer all of the questions, you will receive an award letter for 1.5 hours Continuing Medical Education (CME) credit; 0.15 Continuing Education Units (CEUs); or 1.9 contact hours Continuing Nursing Education (CNE) credit. If you return the form electronically, you will receive educational credit immediately. If you mail the form, you will receive educational credit in approximately 30 days. No fees are charged for participating in this continuing education activity.

INSTRUCTIONS

By Internet

1. Read this *MMWR* (Vol. 52, RR-12), which contains the correct answers to the questions beginning on the next page.
2. Go to the *MMWR* Continuing Education Internet site at <http://www.cdc.gov/mmwr/cme/conted.html>.
3. Select which exam you want to take and select whether you want to register for CME, CEU, or CNE credit.
4. Fill out and submit the registration form.
5. Select exam questions. To receive continuing education credit, you must answer all of the questions. Questions with more than one correct answer will instruct you to "Indicate all that apply."
6. Submit your answers no later than **July 18, 2006**.
7. Immediately print your Certificate of Completion for your records.

By Mail or Fax

1. Read this *MMWR* (Vol. 52, RR-12), which contains the correct answers to the questions beginning on the next page.
2. Complete all registration information on the response form, including your name, mailing address, phone number, and e-mail address, if available.
3. Indicate whether you are registering for CME, CEU, or CNE credit.
4. Select your answers to the questions, and mark the corresponding letters on the response form. To receive continuing education credit, you must answer all of the questions. Questions with more than one correct answer will instruct you to "Indicate all that apply."
5. Sign and date the response form or a photocopy of the form and send no later than **July 18, 2006**, to
   Fax: 404-639-4198 Mail: MMWR CE Credit

ACCREDITATION

Continuing Medical Education (CME). CDC is accredited by the Accreditation Council for Continuing Medical Education (ACCME) to provide continuing medical education for physicians. CDC designates this educational activity for a maximum of 1.5 hours in category 1 credit toward the AMA Physician's Recognition Award. Each physician should claim only those hours of credit that he/she actually spent in the educational activity.

Continuing Education Unit (CEU). CDC has been approved as an authorized provider of continuing education and training programs by the International Association for Continuing Education and Training and awards 0.15 Continuing Education Units (CEUs).

Continuing Nursing Education (CNE). This activity for 1.9 contact hours is provided by CDC, which is accredited as a provider of continuing education in nursing by the American Nurses Credentialing Center's Commission on Accreditation.

Goal and Objectives

This *MMWR* provides recommendations for preventing transmission of human immunodeficiency virus (HIV) by infected persons. These recommendations were developed by CDC, the Health Resources and Services Administration (HRSA), the National Institutes of Health (NIH), the HIV Medical Association (HIVMA) of the Infectious Diseases Society of America (IDSA), and others knowledgeable in HIV prevention. The goal of this report is to provide strategies for persons providing medical care to HIV-infected persons for incorporating HIV prevention into that care. Upon completion of this educational activity, the reader should be able to 1) describe why HIV-prevention efforts in the United States should focus on HIV-infected persons; 2) describe different means of screening HIV-infected patients for HIV-transmission risk behaviors during routine office visits; 3) describe behavioral interventions for HIV-infected persons to prevent HIV transmission; 4) identify reasons for referring HIV-infected persons for additional services; and 5) understand the importance of partner counseling and referral services (PCRS).

To receive continuing education credit, please answer all of the following questions.

1. Whereas HIV-prevention efforts in the United States had focused on persons who were not HIV-infected, emphasis is now placed on prevention services for HIV-infected persons because . . .

A. HIV-infected persons who are aware of their HIV infection tend to reduce behaviors that might transmit HIV to others.
B. bacterial and viral sexually transmitted diseases (STDs) among HIV-infected men and women receiving outpatient care have been increasingly noted, indicating ongoing risky behaviors.
C. optimism regarding the effectiveness of highly active antiretroviral therapy (HAART) for HIV might be contributing to relaxed attitudes toward safer sex practices and increased sexual risk-taking by HIV-infected persons.
D. all of the above.

2. All of the following sex-related behaviors are important to address in risk screening except . . .

A. age at first sexual intercourse.
B. types of sexual activity (oral, vaginal, or anal sex).
C. whether condoms are used.
D. barriers to abstinence or correct condom use.
E. number, sex, and HIV serostatus of partners.

3. Key injection-drug–related behaviors to address in screening include whether the patient has been . . .

A. injecting illicit drugs.
B. sharing needles and syringes or other injection equipment.
C. using new or sterilized needles and syringes.
D. all of the above.

4. Surveys indicate that patients are more likely to discuss risk behaviors if they perceive their clinicians as being . . .

A. comfortable talking about certain topics (e.g., sex and drug use).
B. nonjudgmental, empathetic, and knowledgeable.
C. comfortable counseling patients regarding sexual risk factors.
D. board-certified in infectious diseases.
E. A, B, C.
F. all of the above.

5. Screening HIV-infected patients for STDs has critical public health implications because . . .

A. the presence of STDs often indicates recent or ongoing sexual behaviors that can result in HIV transmission.
B. substantial evidence indicates that certain STDs enhance the risk for HIV transmission or acquisition.
C. identification and treatment of STDs can reduce spread of these infections among groups at high risk (i.e., sex or drug-using networks).
D. all of the above.

6. Which of the following statements regarding screening of HIV-infected patients is not true?

A. At the initial and each subsequent routine visit, all patients should be questioned regarding symptoms of STDs.
B. All men should be screened for gonorrhea.
C. All women and men should be screened for laboratory evidence of syphilis.
D. All women should be screened for trichomoniasis.

7. Clinical and epidemiologic studies have demonstrated the effectiveness of all of the following methods for preventing HIV transmission except . . .

A. sexual abstinence.
B. postexposure prophylaxis for partners.
C. consistent and correct use of condoms.
D. not sharing needles when injecting drugs.

8. Which statement concerning partner counseling and referral services (PCRS) is not true?

A. Certain HIV-infected persons are sexually active after receiving their diagnoses but do not tell their partners about their infection.
B. PCRS helps infected partners gain earlier access to medical evaluation, treatment, and other services.
C. Partners should be told when their HIV exposure occurred.
D. The majority of states have laws and regulations related to informing partners who have been exposed to HIV.

9. Which of the following is not a recommendation related to PCRS?

A. At the initial visit, patients should be asked if all of their sex and needle-sharing partners have been informed of their exposure to HIV.
B. At routine follow-up visits, patients should be asked if they have had any new sex or needle-sharing partners who have not been informed of their exposure to HIV.
C. Patients should be encouraged to talk to the health department disease-intervention specialist regarding sex and needle-sharing partners who have not been informed of their exposure and to arrange for their referral for testing.
D. All partners with whom an HIV-infected person has had sex in the past 15 years should be referred for testing.

10. Which statement is true regarding referring patients for additional services?

A. Achieving behavioral change is often dependent on addressing patient concerns (e.g., homelessness, substance abuse, or mental illness).
B. The majority of injection-drug users are unable to sustain long-term abstinence from drug use without substance abuse treatment.
C. Accessibility and convenience of services predict whether a referral will be completed.
D. All of the above.

11. Indicate your work setting.

A. State/local health department.
B. Other public health setting.
C. Hospital clinic/private practice.
D. Managed care organization.
E. Academic institution.
F. Other.

12. Which best describes your professional activities?

A. Physician.
B. Nurse.
C. Health educator.
D. HIV-prevention counselor.
E. Other.

13. I plan to use these recommendations as the basis for . . . (*Indicate all that apply.*)

A. health education materials.
B. insurance reimbursement policies.
C. local practice guidelines.
D. public policy.
E. other.

14. Each month, approximately how many patients with HIV do you treat?

A. None.
B. 1–5.
C. 6–20.
D. 21–50.
E. 51–100.
F. >100.

15. How much time did you spend reading this report and completing the exam?

A. <1.5 hours.
B. ≥1.5 hours but <2.0 hours.
C. ≥2.0 hours but <3.0.
D. ≥3.0 hours.

16. After reading this report, I am confident I can describe why HIV-prevention efforts in the United States should focus on HIV-infected persons.

A. Strongly agree.
B. Agree.
C. Neither agree nor disagree.
D. Disagree.
E. Strongly disagree.

17. After reading this report, I am confident I can describe different means of screening HIV-infected patients for HIV transmission risk during routine office visits.

A. Strongly agree.
B. Agree.
C. Neither agree nor disagree.
D. Disagree.
E. Strongly disagree.

18. After reading this report, I am confident I can describe behavioral interventions for HIV-infected persons to help prevent HIV transmission.

A. Strongly agree.
B. Agree.
C. Neither agree nor disagree.
D. Disagree.
E. Strongly disagree.

19. After reading this report, I am confident I can identify reasons for referring HIV-infected persons for additional services.

A. Strongly agree.
B. Agree.
C. Neither agree nor disagree.
D. Disagree.
E. Strongly disagree.

20. After reading this report, I am confident I can understand the importance of PCRS.

A. Strongly agree.
B. Agree.
C. Neither agree nor disagree.
D. Disagree.
E. Strongly disagree.

MMWR Response Form for Continuing Education Credit
July 18, 2003/Vol. 52/No. RR-12
Incorporating HIV Prevention into the Medical Care Persons Living with HIV

To receive continuing education credit, you must
1. provide your contact information;
2. indicate your choice of CME, CEU, or CNE credit;
3. answer all of the test questions;
4. sign and date this form or a photocopy;
5. submit your answer form by July 18, 2006.
Failure to complete these items can result in a delay or rejection of your application for continuing education credit.

Valganciclovir Dosing in Children

The U.S. Food and Drug Administration (FDA) is notifying healthcare professionals of new pediatric dosing recommendations for Valcyte (valganciclovir hydrochloride) oral tablets and oral solution. This change is being made to prevent potential valganciclovir overdosing in children with low body weight, low body surface area, and below normal serum creatinine. The revised dosing recommendations are being updated to include an upper limit on the calculated creatinine clearance using the modified Schwartz formula, which is used to calculate the pediatric dose of Valcyte. The FDA has determined that adding an upper limit of 150 mL/min/1.73 m^2 to the creatinine clearance calculated using the Schwartz formula for the determination of pediatric doses can help prevent the potential for Valcyte overdosing. If the calculated pediatric dose of Valcyte exceeds 900 mg, a dose of 900 mg should be given to the child.

The FDA notice is available on http://www.fda.gov/Drugs/DrugSafety/ucm225727.htm#ds and is provided below:

FDA Drug Safety Communication: New dosing recommendations to prevent potential Valcyte (valganciclovir) overdose in pediatric transplant patients

Safety Announcement

[09-15-2010] The U.S. Food and Drug Administration (FDA) is notifying healthcare professionals of new pediatric dosing recommendations for Valcyte (valganciclovir hydrochloride) oral tablets and oral solution. This change is being made to prevent potential valganciclovir overdosing in children with low body weight, low body surface area, and below normal serum creatinine.

The revised dosing recommendations are being updated to include an upper limit on the calculated creatinine clearance using the modified Schwartz formula, which is used to calculate the pediatric dose of Valcyte.

Valganciclovir is an antiviral medication that can be effective for the prevention of cytomegalovirus (CMV) disease in children 4 months to 16 years of age who have undergone a kidney or heart transplant. Cytomegalovirus is a member of a group of herpes-type viruses that can cause disease in different parts of the body.[1] Patients with weakened immune systems, such as organ transplant patients, are particularly susceptible to CMV infection and must take medications such as Valcyte to prevent the disease.

See the Data Summary for the new dosing recommendations for Valcyte.

Additional Information for Patients

- Talk to your healthcare professional about any concerns with your Valcyte dose.
- The side effects from Valcyte overdosing include abdominal pain, vomiting, diarrhea, tremor or seizure.
- Report any side effects you experience to the FDA MedWatch program, using the information in the "Contact Us" box at the bottom of the page.

Additional Information for Healthcare Professionals

- The dosing recommendations for Valcyte in children have changed. The dosing calculation can be found in the Data Summary and in the drug label.
- Be aware of possible valganciclovir overdose in pediatric patients with low body weight, low body surface area, or below normal serum creatinine.
- When calculating the pediatric dose of Valcyte with the modified Schwartz formula, a maximum value of 150 mL/min/1.73 m^2 should be used in the formula.
- When the calculated pediatric dose of Valcyte exceeds 900 mg, a dose of 900 mg should be administered to the child.
- Advise patients to contact a healthcare professional immediately if they experience signs and symptoms of valganciclovir overdose while taking Valcyte.
- Report adverse events involving Valcyte to the FDA MedWatch program, using the information in the "Contact Us" box at the bottom of the page

Data Summary

Healthcare professionals should follow the updated pediatric dosing algorithm in the Valcyte label.[2] The pediatric dose of Valcyte is based on body surface area (BSA) and creatinine clearance (CrCl) derived from a modified Schwartz formula. Under the previous dosing recommendations, pediatric patients with low body weight, low body surface area, and below normal serum creatinine could have a high calculated Schwartz creatinine clearance, resulting in a pediatric dose that approached the adult dose of 900 mg. This type of patient was not routinely observed in the clinical trials used to derive and confirm the pediatric dose, and may have been overdosed according to the previous dosing algorithm. As a result, FDA has updated the dosing algorithm so that when calculating the pediatric dose, a maximum value of 150 mL/min/1.73 m^2 should be used in the formula, even if the calculated Schwartz creatinine clearance exceeds 150 mL/min/1.73 m^2. Furthermore, if the calculated Valcyte dose exceeds 900 mg, a dose of 900 mg should be given to the child.

The revised language in Section 2.3 of the label, *Pediatric Patients*, is as follows (new language underlined)[2]:

Prevention of CMV Disease: For pediatric patients 4 months to 16 years of age who have received a kidney or heart transplant, the recommended once daily dose of Valcyte starting within 10 days of transplantation until 100 days post-transplantation is based on body surface area (BSA) and creatinine clearance (CrCl) derived from a modified Schwartz formula, and is calculated using the equation below:

Pediatric Dose (mg) = 7 x BSA x CrCl (calculated using a modified Schwartz formula). If the calculated Schwartz creatinine clearance exceeds 150 mL/min/1.73 m^2, then a maximum value of 150 mL/min/1.73m^2 should be used in the equation.

$$\text{Mosteller BSA } (m^2) = \sqrt{\frac{\text{Height (cm)} \times \text{Weight (kg)}}{3600}}$$

$$\text{Schwartz Creatinine Clearance } (\text{mL/min/1.73 } m^2) = \frac{k \times \text{Height (cm)}}{\text{Serum Creatinine (mg/dL)}}$$

Where k =

0.45 for patients aged 4 months to < 1 year,

0.45 for patients aged 1 to < 2 years (note k value is 0.45 instead of the typical value of 0.55),

0.55 for boys aged 2 to < 13 years and girls aged 2 to 16 years, and

0.7 for boys aged 13 to 16 years.

In summary, the FDA has determined that adding an upper limit of 150 mL/min/1.73 m^2 to the creatinine clearance calculated using the Schwartz formula for the determination of pediatric doses can help prevent the potential for Valcyte overdosing. If the calculated pediatric dose of Valcyte exceeds 900 mg, a dose of 900 mg should be given to the child.

Summary

The most effective means of preventing human immunodeficiency virus (HIV) infection is preventing exposure. The provision of antiretroviral drugs to prevent HIV infection after unanticipated sexual or injection-drug–use exposure might be beneficial. The U.S. Department of Health and Human Services (DHHS) Working Group on Nonoccupational Postexposure Prophylaxis (nPEP) made the following recommendations for the United States. For persons seeking care ≤72 hours after nonoccupational exposure to blood, genital secretions, or other potentially infectious body fluids of a person known to be HIV infected, when that exposure represents a substantial risk for transmission, a 28-day course of highly active antiretroviral therapy (HAART) is recommended. Antiretroviral medications should be initiated as soon as possible after exposure. For persons seeking care ≤72 hours after nonoccupational exposure to blood, genital secretions, or other potentially infectious body fluids of a person of unknown HIV status, when such exposure would represent a substantial risk for transmission if the source were HIV infected, no recommendations are made for the use of nPEP. Clinicians should evaluate risks and benefits of nPEP on a case-by-case basis. For persons with exposure histories that represent no substantial risk for HIV transmission or who seek care >72 hours after exposure, DHHS does not recommend the use of nPEP. Clinicians might consider prescribing nPEP for exposures conferring a serious risk for transmission, even if the person seeks care >72 hours after exposure if, in their judgment, the diminished potential benefit of nPEP outweighs the risks for transmission and adverse events. For all exposures, other health risks resulting from the exposure should be considered and prophylaxis administered when indicated. Risk-reduction counseling and indicated intervention services should be provided to reduce the risk for recurrent exposures.

Introduction

The most effective methods for preventing human immunodeficiency virus (HIV) infection are those that protect against exposure to HIV. Antiretroviral therapy cannot replace behaviors that help avoid HIV exposure (e.g., sexual abstinence, sex only in a mutually monogamous relationship with a noninfected partner, consistent and correct condom use, abstinence from injection-drug use, and consistent use of sterile equipment by those unable to cease injection-drug use). Medi-

cal treatment after sexual, injection-drug–use, or other nonoccupational HIV exposure* is less effective than preventing HIV infection by avoiding exposure.

In July 1997, CDC sponsored the External Consultants Meeting on Antiretroviral Therapy for Potential Nonoccupational Exposures to HIV. This panel of scientists, public health specialists, clinicians, ethicists, members of affected communities, and representatives from professional associations and industry evaluated the available evidence related to use of antiretroviral medications after nonoccupational HIV exposure. In 1998, DHHS issued a statement that outlined the available information and concluded that evidence was insufficient about the efficacy of nonoccupational postexposure prophylaxis (nPEP) to recommend either for or against its use (*1*).

Since 1998, additional data about the potential efficacy of nPEP have accumulated from human, animal, and laboratory studies. Clinicians and organizations have begun providing nPEP to patients they believe might benefit. In certain instances, health departments have issued advisories or recommendations or otherwise supported the establishment of nPEP treatment programs in their jurisdictions (*2*–*6*). In May 2001, CDC convened the second external consultants meeting on nonoccupational post-exposure prophylaxis to review and discuss the available data. This report summarizes knowledge about the use and potential efficacy of nPEP and details guidelines for its use in the United States.† The recommendations are intended for nonoccupational exposures and are not applicable for occupational exposures.

Evidence of Possible Benefits from nPEP

For ethical and logistical reasons, a randomized, placebo-controlled clinical trial of nPEP probably will not be performed. However, data are available from animal transmission models, perinatal clinical trials, studies of health-care workers receiving prophylaxis after occupational exposures, and from observational studies. These data indicate that nPEP might sometimes reduce the risk for HIV infection after nonoccupational exposures.

* In this report, a nonoccupational exposure is any direct mucosal, percutaneous, or intravenous contact with potentially infectious body fluids that occurs outside perinatal or occupational situations (e.g., health-care, sanitation, public safety, or laboratory employment). Potentially infectious body fluids are blood, semen, vaginal secretions, rectal secretions, breast milk or other body fluid that is contaminated with visible blood.

† Information included in these recommendations might not represent Food and Drug Administration (FDA) approval or approved labeling for the particular products or indications in question. Specifically, the terms safe and effective might not be synonymous with the FDA-defined legal standards for product approval.

Animal Studies

Animal studies have demonstrated mixed results (*1,7*). In macaques, PMPA (tenofovir) blocked simian immunodeficiency virus (SIV) infection after intravenous challenge if administered within 24 hours of exposure and continued for 28 days. PMPA was not as effective if initiated 48 or 72 hours postexposure or if continued for only 3 or 10 days (*8*). Two macaque studies of combination antiretroviral therapy (zidovudine, lamivudine, and indinavir) initiated 4 hours after simian/human immunodeficiency virus (SHIV) challenge and continued for 28 days did not protect against infection but did result in reduced viral load among the animals infected (*9*). In a macaque study designed to model nPEP for mucosal HIV exposure, all animals administered PMPA for 28 days, beginning 12 hours (four animals) or 36 hours (four animals) after vaginal HIV-2 exposure, were protected. Three of four animals treated 72 hours after exposure were also protected; the fourth animal had delayed seroconversion and maintained a low viral load after treatment (*10*).

These findings are consistent with those of macaque studies of the biology of vaginal SIV transmission. After atraumatic vaginal inoculation, lamina propria cells of the cervicovaginal subepithelium were infected first, virus was present in draining lymph nodes within 2 days, and virus was disseminated to the blood stream by 5 days (*11*). Similarly, in another study, SIV-RNA was detected in dendritic cells from the vaginal epithelium within 1 hour of intravaginal viral exposure, and SIV-infected cells were detected in the lymph nodes within 18 hours (*12*). These data indicate a small window of opportunity during which it might be possible to interrupt either the initial infection of cells in the cervicovaginal mucosa or the dissemination of local infection by the prompt administration of antiretroviral medications.

Postnatal Prophylaxis
